25 **Abstract**

26 The necessity to restore rainforest habitats degraded by anthropogenic fires is widely recognized,
27 however, research on restoration approaches has mainly centred on the recovery of forest
28 structural complexity. There is insufficient evidence on the efficacy of restoration methods in the
29 recovery of the faunal diversity and features linked to key ecosystem functions. We assessed the
30 taxonomic diversity and functional trait structure of bird assemblages in undisturbed primary
31 forest and fire-affected habitats undergoing natural regeneration, as well as areas of assisted
32 natural regeneration, in Nyungwe National Park, Rwanda. We compiled bird occurrence data from
33 point-count sampling, and obtained morphological traits for all species in our assemblages using
34 measurements taken from wild birds and museum specimens. We found marked differences in
35 species composition between primary forest habitats and regenerating forest, with similarity
36 increasing over time since perturbation. Taxonomic diversity was higher in primary forest, and
37 similar between the two restoration approaches. Functional diversity was lower in assisted
38 naturally regenerated habitats, although separate analyses within dietary guilds revealed no
39 differences across habitats. Among desired restoration outcomes, tree species diversity was the
40 leading positive driver of avian species diversity, fern coverage exerted negative effects, while
41 canopy cover had a positive but weak influence. Our findings underscore the importance of
42 preventing anthropogenic fires in tropical rainforest since their impacts on ecological processes
43 are not easily reversed, as shown by the lack of improvement in avian diversity metrics under
44 assisted naturally regeneration in relation to natural regeneration. We stress the need to document
45 both floral and faunal recovery in order to aid informed decision-making on restoration methods.

48 functional traits, Nyungwe forest, passive restoration.

49 **1. Introduction**

50 Fire is a natural component of African landscapes, contributing to the formation and maintenance
51 of grasslands and savannas, and the high diversification rate of the associated biota (Cowling,
52 1987; Sodhi et al., 2011; He et al., 2019). Nonetheless, its current frequency and intensity in less
53 fire-adapted wet forests present detrimental effects on ecological processes (King et al., 1997;
54 Cochrane, 2003). Large-scale fires in tropical rainforests have mostly anthropogenic origins, with
55 agricultural and ranching activities being the leading factors (Juárez-Orozco et al., 2017; van Vliet
56 et al., 2012). Indirect drivers, such as fragmentation and deforestation, also increase the
57 occurrence and intensity of fires (Cochrane, 2001; Silva-Junior, 2018). Fire severity is amplified
58 by drought and high temperatures, such as those associated with El Niño years, and is predicted to
59 intensify under future climatic conditions (IPBES, 2019; IPCC, 2019). Where wildfires become
60 chronic and frequent, grasses or opportunistic ferns may occupy the degraded areas, fueling future
61 fires and hampering regeneration for decades (Cohen et al., 1995; Ashton et al., 2001).

62 *Pteridium aquilinum* (L.) Kuhn (bracken fern) is one of the most notorious plants responsible for
63 arrested succession. It is native to all continents and has a distribution spanning temperate and
64 tropical forests and grasslands (Dolling, 1996; Adie et al., 2011). The dominance and persistence
65 of this fern is owed to: i) a dense frond canopy that shades out emerging seedlings; ii) deep
66 ground litter that depletes the seed bank, and constrains colonisation by other species (den Ouden,
67 2000; Ghorbani et al., 2006); iii) a complex rhizome system that resprouts after fires (Ashton et
68 al., 2001); iv) allelopathic effects that minimize plant competition (Gliessman & Muller, 1978);
69 and v) toxic compounds that protect against grazing herbivores (Grime et al., 1988; Ssali et al.,
70 2017).

71 In Bwindi Impenetrable National Park, Uganda, it was found that all sites dominated by the
72 bracken fern had been affected by fires (Ssali et al., 2017). In comparison to the undisturbed
73 forest, the few woody plants that were found within the bracken-dominated area were

74 characterized by small seeds and thick bark. There were also fewer animal-dispersed tree species.
75 Similar results were documented for *Dicranopteris linearis*, an introduced fern in a Sri Lankan
76 rainforest, which proliferated after clearance for swidden agriculture, and repeated fires (Hafeel,
77 1991). In contrast, some other studies in the Neotropics and Afrotropics concluded that bracken
78 ferns played facilitative roles towards late-successional tree species, filtering out pioneer species
79 but providing favourable conditions for germination and establishment of shade-tolerant rainforest
80 species (Gallegos et al., 2015; Ssali et al., 2019).

81 The generally slow performance of natural (“passive”) regeneration in fern-infested areas in the
82 tropics (Shono et al., 2007; Crouzeilles et al., 2017), has sparked the testing of a range of
83 alternative management techniques to accelerate regeneration processes. An experiment
84 conducted by Cohen et al. (1995) in the above-mentioned Sri Lankan lowland rainforest where
85 dominance of *Dicranopteris linearis* had become the stable state, found that techniques
86 comprising rhizome removal and tilling to mix top and mineral soils, eliminated the ferns and
87 enhanced the growth of herbs, shrubs and trees. In Chiapas, Mexico, the monthly removal of the
88 bracken ferns (*Pteridium caudatum*) and sowing or planting seedlings of balsa (*Ochroma*
89 *pyramidale*), a fast growing pioneer tree species, led to the total elimination of the ferns in 18
90 months in plots where balsa occupied at least 11m² per ha (Douterlungne et al., 2013).

91 Due to the high cost associated with the planting of seeds or seedlings (active restoration), the
92 assisted regeneration approach— a less intensive management intervention that often entails the
93 removal of the herbaceous vegetation, the application of fertilizers or herbicides, and the use of
94 artificial perches to enhance propagule supply — has been preferentially applied (Shono et al.,
95 2007; Shoo & Catterall, 2013; Elliott, 2016; Chazdon, 2017). Assisted natural regeneration was
96 found to be effective in increasing substantially the canopy cover, species richness, and stem
97 density of woody plants in an Australian subtropical forest that was previously cleared for grazing
98 (Uebel et al., 2017).

99 Although a range of techniques have long been practiced by indigenous communities to
100 regenerate forests (Dugan et al., 2003; Douterlungne et al., 2010), there is scant information on
101 their performance in the recovery of animal species diversity, and features linked to ecological
102 functions. A search in the bibliographic database, ISI Web of Science employing the terms “fern
103 or Pteridium & tropic* forest & restor*”, for the period 2010 to 2020, covering Ecology,
104 Environmental sciences, Forestry, Biodiversity Conservation, and related fields, gave 210
105 research items that contained the search terms in their topics but none that evaluated the effects of
106 restoration approaches on the fauna. Instead, studies largely focused on distribution of the fern
107 species, control methods, and the vegetation assessment following restoration interventions. It is
108 thus too early to generalize as to the efficiency of a particular restoration technique in regard to
109 the recovery of animal diversity, especially in the Afrotropics where there has been less research
110 coverage (Reij & Garrity, 2016; Shoo & Catterall, 2013). This paucity of information also applies
111 to the wider restoration field since many existing studies are based on comparisons of projects
112 with different timeframes or end-goals (Larkin et al., 2019).

113
114 Our study aims to address this gap by comparing both naturally regenerated and assisted naturally
115 regenerated habitats to primary forest (areas of no major disturbance) within the same landscape.
116 The advantage of our method is that we are not comparing the outcome of restoration efforts to a
117 pre-disturbance state, an approach which would not account for the dynamism of ecosystem
118 processes, such as the variabilities induced by anthropogenic climatic changes (Holl & Aide,
119 2011). Instead, we are carrying out a spatial comparison using birds to assess the faunal recovery
120 with particular reference to their functional roles within the ecosystem. Birds provide a well-
121 established indicator group of the vitality of ecosystems that are highly relevant to restoration
122 studies since the ecosystem services performed by birds, such as seed dispersal, pollination and

123 herbivory control combine to accelerate the recovery of degraded forest landscapes (Şekerciöğlü,
124 2012; Roels et al., 2019).

125
126 We conducted our study in Nyungwe National Park (Fig.1), a tropical montane rainforest in the
127 southwest of Rwanda. In proportion to its surface area, Rwanda has made the largest pledge to the
128 Bonn Challenge. A commitment of 2 Mha was made, representing an area larger than that
129 currently supporting agricultural or forestry activities (Fagan et al., 2020). Rwanda has also been
130 classified among the top restoration hotspots based on benefits and feasibility factors (Brancalion
131 et al., 2019). One of the restoration projects undertaken includes the restoration of burnt areas
132 within the Nyungwe National Park. The project has used assisted natural regeneration methods to
133 increase tree cover and tree species diversity by combatting the opportunistic fern *Pteridium*
134 *aquilinum*, which inhibits forest regeneration processes (Masozera & Mulindahabi, 2007).

135
136 In the present study, we asked two primary questions. First, how do avian species composition,
137 diversity and functional trait structures vary across three different habitat types? We made three
138 predictions regarding this question: i) the three habitats (naturally regenerated, assisted naturally
139 regenerated and primary forest) will have distinct species composition, and different amounts of
140 taxonomic and functional diversity; ii) avian diversity will be higher in assisted naturally
141 regenerated than in naturally regenerated habitats; both will converge towards the composition
142 and diversity of undisturbed primary forest habitats over time (Derhé, et al., 2016); and finally iii)
143 there will be a difference in the recovery of major guilds occupying naturally regenerated and
144 assisted naturally regenerated sites, with frugivores in both habitats slower to recover due to their
145 preference for a continuous forest cover (Farwig et al., 2017). Second, to what extent do changes
146 in vegetation generated by the assisted restoration project influence avian taxonomic and
147 functional diversity across the habitat types? We hypothesized that: i) vegetation complexity and
148 stature drive increasing avian diversity, and; ii) the proportion of ferns will be the major negative

149 driver of avian taxonomic diversity and will lead to reduced avifaunal community trait structure,
150 particularly for the regenerated habitats (cf. Gould & Mackey, 2015, Ikin et al., 2019).

151 **2. Methods**

152 **2.1 Study site description**

153 The study was conducted in Nyungwe National Park (Nyungwe NP), a tropical montane rainforest
154 of 1,019 km² in south-western Rwanda. Its elevational range spans 1,600–2,950 m. The mean
155 annual rainfall spans 1500 – 2500 mm, and the average minimum temperature is 10.9⁰C, whilst
156 the maximum is 19.6⁰ C (Sun et al., 1996; Seimon, 2012).

157 In the last twenty-three years, anthropogenic fires in the Nyungwe forest have ravaged more than
158 12% of the forest (Weber et al., 2005; Nyungwe National Park, 2018, 2019). In most instances,
159 the fires were set accidentally by people engaging in illicit activities, mainly honey collection,
160 wood collection, hunting and mining (Barnett and Dardis, 2017). The fire management strategies
161 implemented in the Nyungwe NP have considerably lowered the annual tally of burnt areas from
162 155.5 ha and 234.5 ha in 2003 and 2004, to 8.8 ha and 5 ha in 2018 and 2019, respectively
163 (Nyungwe National Park, 2018, 2019). Nonetheless, in extensive parts of the forest, sites that
164 were occupied by a tall canopy forest comprising late-successional forest species, dominated by
165 *Syzygium guineense*, have been replaced by dense thickets of opportunistic ferns, typically
166 *Pteridium aquilinum*, leading to arrested succession (Masozera & Mulindahi, 2007).

167 In early 2000, the park management and conservation partners initiated trials to determine the
168 most efficient restoration method in terms of seedling establishment and cost-effectiveness
169 between: 1) cutting the fern vegetation and planting indigenous forest tree seedlings from tree
170 nurseries established outside of the forest, and 2) removing the ferns to facilitate germination of
171 any viable seeds from the soil seed bank or seeds that were newly dispersed by various agents
172 (assisted natural regeneration) (Weber et al., 2005). Trial results supported the latter method, and

173 the systematic removal of the fern vegetation in every three months over a three-year period was
174 recommended (Masozera and Mulindahabi, 2007). After this period, seedlings were strong and
175 tall enough to survive, shade-out and outcompete the fern vegetation.

176 Clearing of restoration sites followed the nucleation technique to limit soil disturbances. Per
177 hillside, only plots ranging from 250 to 500 m² were cleared. It was envisaged that with time, the
178 restored canopy would expand outwards, and shade-off the remaining ferns. Since 2003, the
179 assisted natural-regeneration method has been applied in all restoration interventions in the
180 Nyungwe NP. Restoration sites were prioritized based on the scarcity of trees and the accessibility
181 and visibility from the main road (Masozera & Mulindahabi, 2007). The total area of plots that
182 have been treated amount to 250 ha (WCS, pers. comm). In most cases, the shade-intolerant
183 pioneer species (particularly *Macaranga kilimandscharica*) grow immediately after the treatment
184 was applied. The recruitment of shade-tolerant primary forest species follows after the canopy
185 starts to close (P.N. pers. obs.). Although annual monitoring of the vegetation cover in the
186 restored plots has been conducted as part of the management of the park, no scientific study has
187 hitherto been conducted to assess the recovery of the avifauna.

188

189

190 **2.2 Avian sampling**

191 Sampling was conducted in naturally regenerated habitats (NR), assisted naturally regenerated
192 habitats (AR), and in primary forest (PF), which is considered herein as the reference state. Sites
193 were classified as primary forest if they contained old growth forest, i.e. late stages of stand
194 development, with little human-induced degradation (Putz and Redford, 2010). In Nyungwe NP,
195 such sites were characterized by tree species such as *Syzygium guineense*, *Strombosia schefflera*,
196 and to a less extent *Entandophragma excelsum*. Both NR and AR were disturbed by

197 anthropogenic fire events that occurred between 1996 to 2017. Most sites were burnt during the El
198 Niño period of 1997–1998. A few sites experienced a second fire between 2004 and 2017.
199 Sampling sites were predefined after a series of meetings with key researchers and managers
200 involved in the fire management and restoration programs of the park. The criteria for site
201 selection included safe road conditions and the general safety of the area.

202 To record birds, point-counts of 100 m radius were conducted in naturally regenerated habitats,
203 assisted naturally regenerated habitats, and primary forest. At each point, bird species seen or
204 heard were recorded for a duration of 10 minutes by one observer with 30 years of bird survey
205 experience in the Nyungwe landscape. Ten point-counts were conducted within the same site
206 (same habitat) per day, starting at 5:45 and finishing at 10:30 am.

207 A hundred point stations were sampled in each habitat from November 2017 to February 2018
208 (wet season), and they were repeat-sampled between June and August 2018 (dry season), bringing
209 the total to 600 point-counts. Regenerating forests were further classified by age class, relating to
210 the time since a fire incidence for NR habitats, and the year of restoration for AR habitats. Within
211 NR, 30 point stations were established in young habitats (<10 years), and 70 point stations in mid-
212 age habitats (10–20 years), while in AR, 50 points stations were established in each age class.
213 Fewer points were conducted in young NR due to the low representation of this age class in the
214 Nyungwe NP. A minimum distance of 200 m was maintained between points to reduce the risk of
215 double counting of birds and to maintain statistical independence.

216 **2.3 Vegetation assessment**

217 At each plot, a smaller circular plot of 20 m radius was established to record vegetation attributes
218 targeted by the restoration project. Trees of diameter at breast height (DBH) >5 cm were counted,
219 identified to species level, and their height was measured using a laser range finder. The trees
220 were then sorted into DBH classes of 5–14, 15–50, 51–100, 101–200, and > 200 cm. Canopy

221 cover was estimated using a spherical densiometer. Four readings were taken from each cardinal
222 direction, and the mean was used as the final record. The percentage of the fern coverage inside
223 the plot was visually estimated, with 0% indicating absence and 100% signifying total occupation
224 by the ferns. One botanist and an assistant conducted the vegetation survey, and they sampled one
225 to two plots behind the bird survey team. As with the avian survey, sampling was carried out in
226 the wet season, and a replication was done in the dry season.

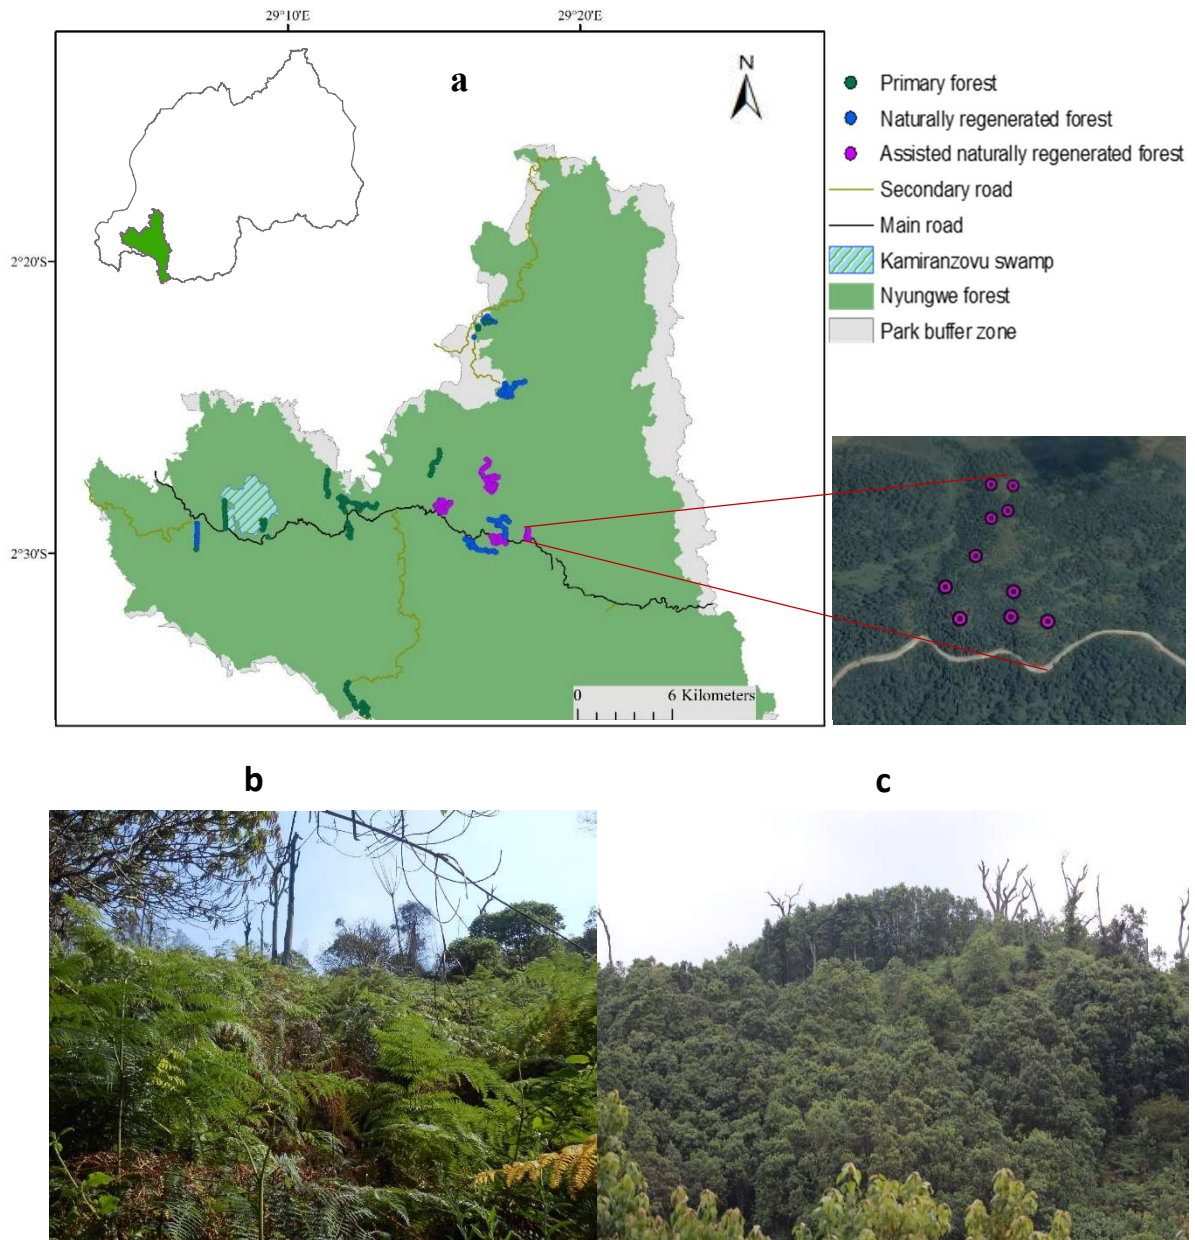

227

228

229

230

 235 assisted naturally regenerated forest dominated by *Macaranga kilimandscharica* (AR; c). 10 points counts
 236 were conducted within the same site per day. Base map sources: WCS, Rwanda, Google Earth.

237
 238
 239

240 **2.4 Functional traits collection**

241 Biometric data of study birds were measured from wild birds or museum specimens following a
242 standardized protocol elaborated in Bregman et al. (2016). The measurements included: bill
243 length, width and depth, which are indicative of the trophic niche; tarsus length, hand wing index,
244 tail length, which are indicative of locomotory and flight capabilities; and body size (measured as
245 body mass in grams), which indicates energy requirements (Hutchinson, 1959; Grant & Grant,
246 2006; Sheard et al. 2020). Dietary data were obtained from Wilman et al. (2014), who grouped
247 birds according to their preferred food items as follows: Fruit-Nectar, Invertebrates, Omnivore,
248 Plant-Seed matter, Vertebrate-Fish-Scavengers. The foraging stratum was obtained from Vande
249 weghe and Vande weghe (2011).

250 **2.5 Data analysis**

251 Except where mentioned, the sampling unit of analysis was five adjacent points within the same
252 habitat. Twenty samples (100 points) were collected per habitat. The values are pooled for avian
253 diversity and averaged for vegetation attributes. For analyses involving avian and vegetation data,
254 avian diversity metrics were calculated based on birds recorded within 20 m radius of the point
255 station instead of the 100 m radius, corresponding to the size of the vegetation assessment plots. A
256 previous study based on the same dataset found no seasonality effects (Rurangwa et al., in review),
257 hence data for the two sampling seasons were averaged to avoid pseudo-replication.

258 To explore the similarity in species composition across habitat type and age, a nonmetric
259 multidimensional scaling (NMDS) ordination analysis based on the Bray-Curtis similarity measure
260 was used, followed by an ANOSIM test which reveals the degree of significance of the similarities
261 among the habitat groups. Both analyses were performed using the Community Analysis Package
262 5 (Seaby et al., 2014).

263 To measure the taxonomic diversity within each habitat, the exponential of Shannon entropy and
264 pairwise beta diversity (measured using Sørensen dissimilarity, and partitioned into spatial
265 turnover and nestedness-resultant dissimilarity, based on a presence and absence matrix: Baselga
266 (2012)) were computed using the iNext, Vegan and Betapart R packages (Oksanen et al., 2010;
267 Baselga and Orme 2012; Hsieh et al., 2016).

268 To assess the within-habitat variations of beta diversity components, a permutation analysis of
269 multivariate dispersions (PERMDISP; Anderson et al., 2006) using 999 iterations was also
270 performed, followed by an ANOVA, and a Tukey's test.

271 To investigate how total beta diversity and its components change with the habitat regeneration
272 time between pairs of the samples within AR and NR habitats (a sample here was based on the
273 average of two replicates of 10 adjacent points belonging to the same site, and hence same
274 regeneration time, amounting to 20 samples and 190 pairwise comparisons), three separate
275 correlation analyses were conducted. Since the variables were pairwise distance matrices that
276 violated the linear regression assumption of independence, Pearson correlations were obtained
277 using Mantel tests (Baselga, 2010; Aspin et al., 2018).

278 To quantify functional diversity, functional dispersion (FDis), a distance-based multivariate metric
279 that measures the spread of species in a trait space (Laliberté & Legendre, 2010), and the
280 community-weighted mean (CWM) were calculated for samples within each habitat. CWM was
281 calculated for the traits that are indicative of energy requirements, feeding, locomotion and dispersal
282 functions. Gower's distance was used as a measure of distance as some of the traits were categorical.
283 We used the FD package (Laliberté et al., 2014) and followed the analytical steps described in
284 Bregman et al. (2016). We determined differences in taxonomic and functional diversity metrics
285 across habitat types by bootstrapping the mean and confidence intervals (bias corrected) using 10
286 000 randomizations for samples within each habitat. Separate analyses were conducted for data

287 subsets containing invertivorous (invertebrates constitute at least 60% of the diet), and frugivorous
288 guilds (fruit constitutes at least 60% of the diet), following Wilman et al. (2014). The two guilds
289 were selected to evaluate maintenance of herbivory control, and seed dispersal functions under the
290 two regeneration methods.

291 We modelled separately the influence of the extent of ferns, canopy cover, and tree diversity on
292 avian species diversity (measured as the exponential of the Shannon entropy), and abundances
293 across the three habitat types. Although tree size (DBH), and canopy height were recorded, they
294 were removed from further analyses due to the high correlation between the two and with tree
295 diversity (Pearson's $R > 0.7$; Fig.A.1). Vegetation attributes were standardized to mean of 0 and
296 standard deviation of 1. We checked for the extent of collinearity among vegetation attributes by
297 computing the variance inflation factor (VIF). VIF values for the model predictors ranged
298 between 1.2 and 2.0.

299 Since the assumptions of standard linear regression were met for the taxonomic diversity variable,
300 we performed a Gaussian multiple linear regression analysis for species diversity, while a
301 generalised linear model (Quasi-Poisson family) was used with the species abundance response
302 variable to account for overdispersion. We then performed model selection based on AIC_c
303 (Akaike Information Criterion corrected for sample size). $QAIC_c$, a modified AIC_c for Quasi-
304 Poisson models with overdispersion, was used for the abundance model. Spatial autocorrelation
305 was diagnosed on model residuals using Moran's I test and was not significant for both taxonomic
306 diversity and abundance metrics ($P > 0.05$). We averaged all models within ΔAIC or $\Delta AIC_c < 2$ of
307 the most parsimonious model. The models were constructed using the Package "lme4", and
308 "MuMin" (Bates, Maechler et al., 2014; Barton, 2019).

309 To explore the same relationship but with functional traits, a combination of the RLQ and Fourth-
310 corner analyses (Dolédec et al., 1996) was performed using the R package "ADE4" (Dray et al.,
311 2007). Both the RLQ and Fourth-corner analyses hinge on the analysis of a fourth-corner matrix

312 obtained by crossing variables from three tables. In this case the R table was derived from
313 vegetation attributes, the L table from species abundance across samples, and the Q table from
314 species traits. Although the two methods' inputs are similar, their outputs differ substantially
315 (Dray et al., 2014). The RLQ is a multivariate approach and explains the interaction between the
316 three tables containing species abundance, traits and environmental attributes through ordination
317 scores (Dray et al., 2002), whereas the fourth-corner analysis focuses on the interaction between
318 an individual trait and one environment attribute at a time (Dray and Legendre, 2008). Combining
319 the two methods helps to unveil which traits have changed as a result of the regeneration
320 pathways (Dray et al., 2014). Except where otherwise mentioned, all statistical analyses were
321 performed using R version 3.6.1 (R CoreTeam, 2019).

322 **3. Results**

323 **3.1 Species composition**

324 The study recorded 4,565 bird individual sightings belonging to 122 species. The number of
325 individuals per sample ranged from four individuals and three species in the assisted naturally
326 regenerated habitats (AR) to 107 individuals and 34 species in the primary forest (PF). The
327 highest total numbers of individuals and of species were recorded in PF (n = 1,954; species =
328 102), followed by NR (n = 1,322, species = 83) and AR (n= 1,289, species: 58) (Table A1).
329 *Bradypterus cinnamomeus*, *Zosterops senegalensis*, and *Apalis personata* were well represented
330 across all habitat types and constituted 17% of all individuals. *A. personata* was the most
331 frequently encountered Albertine Rift endemic species.

332 The dominant dietary guild in terms of species richness and individual sightings was invertivores,
333 with 72 species and 2,675 individuals, followed by omnivores, with 15 species and 681
334 individuals, and frugivores, with 14 species and 578 individuals. The top three recorded species
335 among invertivores were: *B. cinnamomeus*, *A. personata*, and *Phylloscopus laetus* (endemic),

336 frugivores: *Z. senegalensis*, *Ruwenzornis johnstonii* (endemic), *Arizerocicla nigriceps*, and
337 omnivores: *Onychognathus walleri*, *Eurillas latirostris*, and *Cinnyris regius* (endemic). Although
338 rarefaction curves based on species richness did not level off in any of the habitats, those based on
339 species diversity plateaued, particularly in AR habitats, showing the adequacy of sampling efforts
340 (Fig. A.2).

341
342 NMDS revealed high segregation of PF from the other two habitat types, and considerable overlap
343 between NR and AR samples (Fig. 2). The ANOSIM test (Table A.2) concurred with the NMDS
344 ordination, showing significant differences between most habitat types ($r = 0.3$, $P = 0.001$). As
345 expected, mid-aged regenerating communities (MNR, and MAR) were more similar to PF
346 communities than young ones (YNR, and YAR). The lowest similarity was between PF and
347 young NR ($r = 0.68$, $P = 0.001$). All pairwise comparisons were significant at $P = 0.05$, except for
348 MNR–MAR, and MNR–YNR.

349

350

351

352

353 **Figure 2** Two dimensional non-metric multidimensional scaling (NMDS) based on species raw
 354 abundances within primary forest (green circles; N = 20), young naturally regenerated (blue triangle; N=
 355 6), mid-aged naturally regenerating (blue circles, N = 14), young assisted naturally regenerated (purple
 356 triangles; N = 10), and mid-aged assisted naturally regenerated (purple circles; N=10). The left-most blue
 357 triangle represents a sample with rare species: *Dendropicos griseocephalus* which was recorded once, and
 358 *Buteo buteo*, which was only recorded twice. The most negative sample on Axis 2 contains the fewest
 359 individuals (11; the mean is 42). The two blue samples with the highest score on axis 1 were located in
 360 close proximity to PF habitats. Each sample is an aggregate of 5 adjacent point counts sampled twice (in
 361 the wet and dry seasons) and then averaged.

362

363 3.2 Beta diversity

364 The within-habitat variation was only significant for total beta diversity β_{sor} ($F_{2,27}=5.37$, $P =$
 365 0.01), and the difference was highest between NR and AR ($P = 0.0079$). Using Mantel tests for
 366 samples within AR and NR habitats, we found a moderate positive correlation between difference
 367 in the regeneration time (time since a fire incidence or since restoration interventions) and the
 368 total beta diversity ($R = 0.35$, $P = 0.0002$), a weak positive relationship with species turnover (R

369 = 0.23, $P = 0.01$) and no significant relationship with nestedness-resultant dissimilarity ($R = 0.11$,
370 $P = 0.11$, Fig. 3a-c).

371

372

373 **Figure 3.** Correlation of pairwise dissimilarities in species composition of avian communities (species =
374 91) and habitat regeneration time (difference in time since fire or since restoration activities) of naturally
375 regenerated and assisted naturally regenerated habitats within Nyungwe National Park, Rwanda. **a:** Total
376 beta diversity (β_{sor}), **b:** turnover (β_{sim}), and **c:** nestedness-resultant dissimilarity (β_{sne}). The correlation
377 coefficients and p-values were generated by Mantel tests. Asterisks indicate statistically significant
378 differences: ‘*’ 0.05, ‘***’ 0.01, ‘****’ 0.001. The analysis is based on 20 samples, whereby a sample
379 constitutes 10 adjacent points within the same habitat sampled twice (once in each season) and averaged.

380

381 3.3 Avian richness and diversity estimates across habitat types and dietary guilds

382 Taxonomic and trait-based metrics differed across habitat types except for community weighted
383 mean (CWM) of the dispersal traits (Table 1). For the overall category (all birds combined) and
384 within major dietary guilds, Taxonomic diversity (exponential of Shannon entropy) was
385 significantly different between PF and NR, and PF and AR, but did not differ between NR and
386 AR. For the trait-based metrics, variation within the invertivores was similar to the overall pattern

387 except for the functional dispersion index (FDis). FDis values were significantly lower in AR
388 when data for all birds were combined (Table 1). A shift towards higher mean values in AR than
389 in PF was registered for the traits indicative of body size within invertivores, and the trophic axis
390 within frugivores.

391

392 **Table 1.** Comparisons of Taxonomic diversity and functional diversity metrics for bird communities sampled in primary forest (PF), naturally
 393 regenerated sites (NR), and assisted naturally regenerated sites (AR) in Nyungwe National Park, Rwanda. Sample sizes (N = 20) are equal
 394 among habitat types. Each sample is a pool of 5 adjacent point counts, each sampled twice over the wet and dry seasons and averaged. Statistical
 395 significance was tested using bootstrap analysis with 10 000 randomisations (see text). Confidence intervals are not included in the table for
 396 readability purposes. Overall, the range of the metrics were as follows: Taxonomic diversity: 10.9–18.46; FDis: 0.177–0.21; CWM.Trophic:
 397 0.027–0.129; CWM.Dispersal: 12.85–16.26; CWM.Locomotion: -0.097–0.076; CWM.Size: 0.196–0.581.

398

	Overall			Invertivores			Frugivores		
	PF	NR	AR	PF	NR	AR	PF	NR	AR
Taxonomic diversity	17.03^a	11.72^b	12.00^b	11.04^a	7.36^b	8.45^b	2.54^a	1.46^b	1.49^b
FDis	0.20^a	0.20^a	0.18^b	0.13	0.14	0.13	0.06	0.09	0.07
CWM.Trophic	0.09	0.08	0.06	0.26	0.26	0.23	-0.01^a	0.05^{ab}	0.06^b
CWM.Dispersal	15.35	14.05	13.74	12.89	11.86	11.97	15.10	12.44	12.15
CWM.Locomotion	-0.05^a	0.03^b	0.04^b	0.04^a	0.29^b	0.22^{ab}	0.06	0.12	0.13
CWM.Size	0.31^a	0.42^{ab}	0.53^b	0.30^a	0.34^{ab}	0.50^b	-0.05	0.05	-0.20

399 Note. Taxonomic diversity was measured as the exponential of the Shannon diversity index. FDis: Functional dispersion, and CWM: Community weighted
 400 mean of traits indicative of key ecological functions. The metric values are ranked from a-c; in the absence of significant differences at $\alpha = 0.05$, they
 401 are assigned the same letter. Bold values signify statistically significant differences.

402 **3.4 The relationship between avian taxonomic diversity and vegetation attributes**

403 Vegetation attributes were in most cases higher in PF, and mostly lowest in AR (Table A3).

404 An average of the most parsimonious model and a supporting model within $\Delta AIC_c < 2$ for PF, NR
 405 and AR habitats explained a moderate amount of variation ($AdjR^2$: 0.38) and showed tree
 406 diversity as the leading driver of avian taxonomic diversity with a higher Beta coefficient and
 407 relative importance values of 0.82, and 0.96, respectively, followed by the extent of ferns, which
 408 had a Beta coefficient of -0.68 and an importance of 0.75. Canopy cover exerted a weak positive
 409 influence, with a Beta coefficient of 0.23 and an importance value of 0.37 (Table 2, Fig. A3). The
 410 pattern was consistent for species abundance, however, tree diversity and the extent cover of ferns
 411 had lower importance values of 0.74, and 0.51, respectively (Table A4).

412
 413 **Table 2** A multiple regression analysis showing the relationship between vegetation parameters and avian
 414 species diversity (exponential of Shannon entropy) for sample plots (n= 20 per habitat) within primary
 415 forest, naturally regenerated forest and restored forest in Nyungwe National Park, Rwanda. The average
 416 and relative importance of model parameters of the linear regression models within $\Delta QAIC_c < 2$ are given
 417 for each metric. The relative importance is computed as the total of Akaike weights over all selected
 418 models containing the explanatory attribute. Importance values close to one indicate a stronger effect
 419 whilst those close to 0 indicate weaker effects.

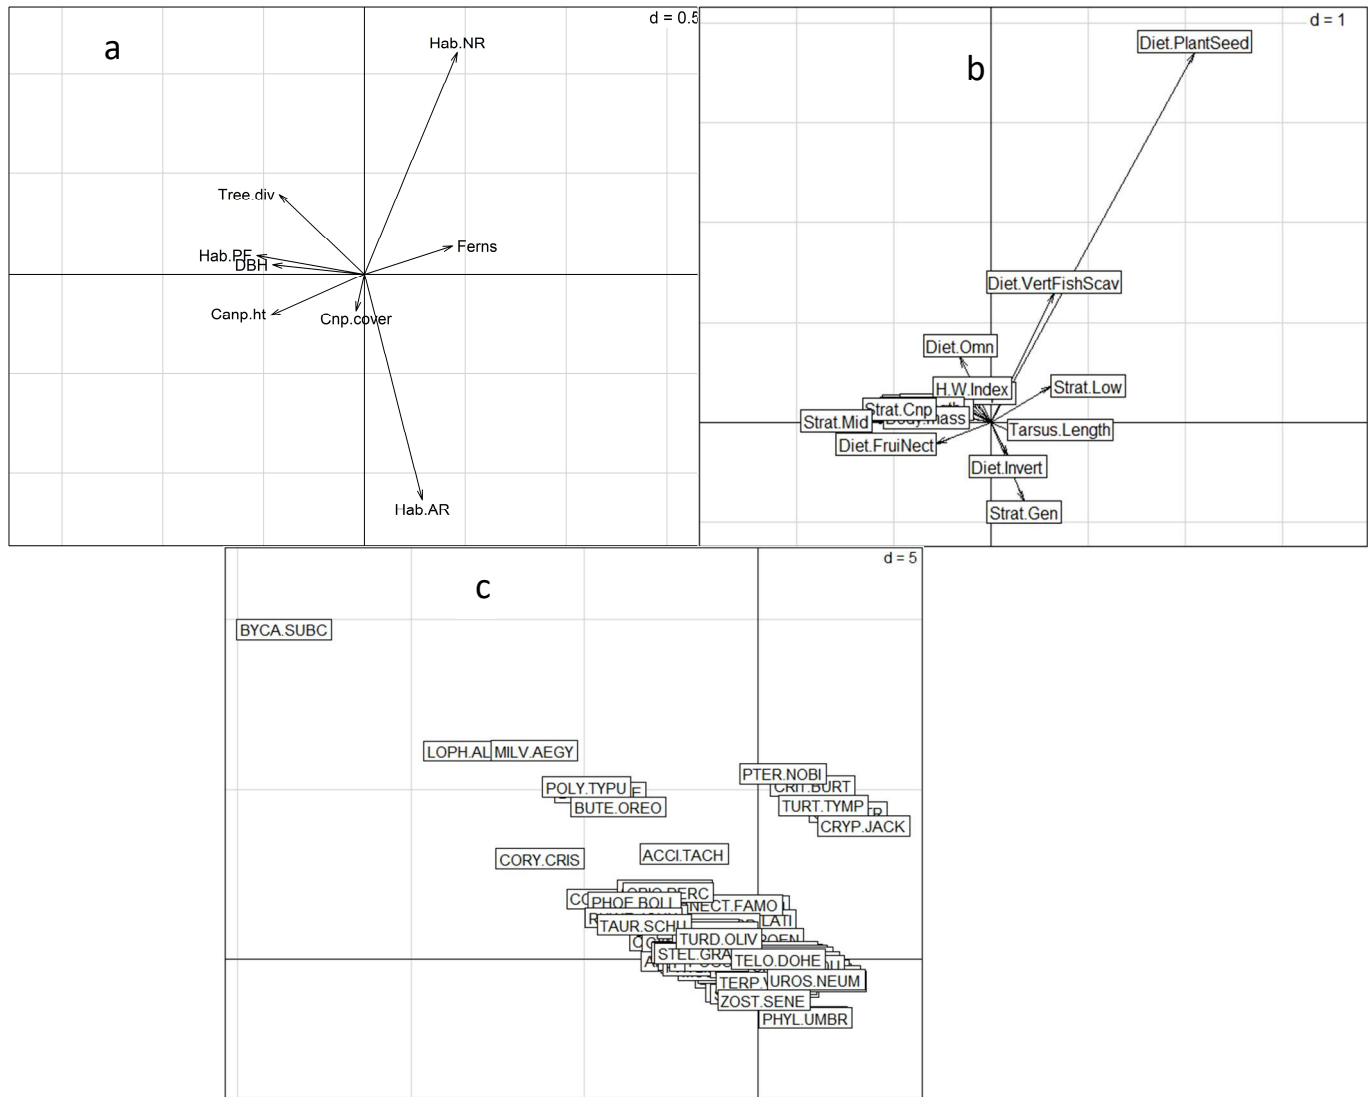

Species diversity								
Models	Cnp.cover	Ferns	Tree.div	adjR ²	logLik	AICc	delta	weight
1		-0.71	0.80	0.37	-120.74	250.20	0.00	0.46
2	0.23	-0.60	0.86	0.38	-120.32	251.76	1.55	0.21
Average	0.23	-0.68	0.82					
Importance	0.37	0.75	0.92					

420 Note. Cnp.cover = Canopy cover, Ferns = cover of ferns, Tree.div = tree diversity, and it is computed as
 421 the exponential of the Shannon diversity index.

422
 423

424 3.5 The relationship between avian traits and vegetation attributes

425 The RLQ analysis showed on the first axis a gradient from primary forest sites (PF) with tall,
426 large trees and a high diversity of trees, to sites with low values for each and with higher fern
427 coverage (Fig. 4a). By this analysis, the PF habitat is associated with species of birds whose traits
428 indicate mid-strata and canopy use (strat.Mid, strat.Cnp), and fruit-nectar and omnivore diets (Fig.
429 4b-c). Typical species include *Bycanistes subcylindricus*, *Lophoceros alboterminatus*,
430 *Corythaeola cristata* (Fig. 4c, and Table A.1). The second axis is largely structured by the
431 naturally regenerated habitat (NR) and the assisted naturally regenerated habitat (AR). The NR
432 habitat is associated with the right upper quadrant and low canopy heights and high fern cover,
433 and the AR habitat occupies the bottom right quadrant, featuring sites of low tree diversity, and
434 low canopy cover. NR sites feature birds with a plant-seed diet such as *Pternistis nobilis*, and
435 *Turtur tympanistria*, and *Cryptospiza jacksoni* (ARE), while AR sites feature in particular,
436 invertivores and species that forage across multiple strata (Strat Gen).

437

438

439 **Figure 4** RLQ analysis showing relationships between avian traits and habitat variables related to
 440 restoration activities of fire-degraded sites within Nyungwe NP, Rwanda. **a:** Coefficients for the habitat
 441 variables, **b:** coefficients for the avian trait variables, **c:** scores of bird species. The “d” values in the upper
 442 right corner indicates the scale grid dimension for comparison across the three plots. Axes 1 and 2
 443 accounted for 85.6% and 12% of the projected inertia, respectively. Hab: Habitat, Cnp.cover: Canopy
 444 cover, Tree.div: Tree diversity, DBH: Diameter at Breast height, Canp.ht: Canopy height, FruNect:
 445 Fruit/Nect, Invert: Invertivore; VertFishScav: Vertebrate/Fish/Scavenger, Strat.Low: Lower stratum,
 446 Strat.Mid: Medium stratum, Strat.Gen: multiple strata, Omn: Omnivore; H.W.Index : Hand Wing Index.
 447 Full names of species and their scores are given in Table A.1.

448
449 The fourth corner analysis did not reveal any significant associations between traits and
450 environmental attributes when the p-values are adjusted for multiple comparisons using the
451 Benjamini and Hochberg method (without this adjustment, PF and AR are significantly associated
452 with fruit-nectar diet, and multiple strata, respectively). The multivariate permutation test
453 combining both the RLQ and Fourth-corner approaches, which was performed to determine the
454 overall significance of the traits-environment relationships, showed a significant relationship for
455 model 2— permutation of sites ($P = 0.00002$), and a non-significant relationship for model 4—
456 permutation of species ($P = 0.50$).

457

458 **4. Discussion**

459 **4.1 Dynamism of avian taxonomic diversity with forest regeneration**

460 As predicted, primary forest (PF), naturally regenerated (NR), and assisted naturally regenerated
461 habitats (AR) had distinct avian species assemblages. Although there was a degree of overlap in
462 composition between the regenerated habitats and across age classes, bird assemblages of mid-
463 aged habitat were more similar to those within primary forest habitats than young ones. The role
464 of fire in creating different bird communities from those of undisturbed forest has also been
465 observed in the Amazon forest (Barlow and Peres, 2004; Barlow et al., 2006). Similarly, Gould
466 and Mackey (2015), in their study in tropical northern Australia, noted differences in avian
467 assemblages between undisturbed woodlands and revegetated sites that had been cleared for
468 mining, and also between age categories of the revegetated habitats.

469 The tendency of increased similarity in species composition with time between regenerated
470 habitats and the primary forest noted by this study is reaffirmed by the correlation of pairwise beta
471 diversity with difference in time since fire disturbances. The increase in similarity was principally

472 driven by the turnover of species, however, the relationship was of only moderate strength,
473 probably due to the fact that the assessment was carried out within a short time interval, since the
474 longest regeneration time was two decades. Another explanation could be the high within-habitat
475 variation in avian species composition exhibited by naturally regenerated habitats, which may
476 reflect the varying intensity and recurrence of the fires resulting in habitats of different forest
477 textures. The slow recovery of disturbed habitats was also noted in a study by Shoo et al. (2016)
478 in the wet tropics of Australia, where they found that regenerated sites recovered forest structure
479 attributes such as canopy cover of old growth levels within 40 years, but that at this point the
480 wood volume, the richness of plant species and functional diversity levels were each less than half
481 those found in the old-growth forest.

482 **4.2 Mixed responses of avian diversity features linked to ecosystem functions**

483
484 The species diversity of both invertivores and frugivores were comparable between the naturally
485 regenerated and assisted regenerated habitats, but lower than the levels in primary forest, which
486 implies reduced invertebrate herbivory regulation and seed dispersal services in the regenerated
487 habitats. This might have more consequences in young naturally regenerated habitats, which were
488 structurally and compositionally simplified due to the high coverage of ferns and a paucity of
489 remnant trees, leading to reduced ecological niche space within these habitats. Although tree
490 cover and fruiting were much more restored in assisted regenerated sites, the fact that restoration
491 was done in patches of typically around 500m² may deter frugivores whose reliance on a
492 continuous forest cover has been noted (Farwig and Berens, 2012; Farwig et al., 2017). The high
493 density of young trees within restored patches and little herbaceous understorey may also reduce
494 the permeability of these patches to invertivore birds with gap preferences such as *Caprimulgus*
495 *poliocephalus* and *Bathmocercus rufus* (Vande weghe & Vande weghe, 2011). These species were
496 only recorded in NR and PF, illustrating why AR sites were associated with generalists in terms of
497 foraging stratum.

498 The lower levels of avian taxonomic diversity in regenerating habitats did not much affect the
499 functional dispersion when the analysis was conducted for separate dietary guilds. One reason
500 could be the functional redundancy exhibited by tropical forests (Cooke et al., 2019). For instance,
501 species exclusive to primary forest in this study had a similar trait structure to those found in
502 naturally regenerated and assisted regenerated habitats, including: *Tauraco schuetti*, a frugivorous
503 large-bodied species which is sympatric to the *Ruwenzorornis johnstoni* commonly found in all
504 habitats, and *Stelgidillas gracilirostris*, which belongs to the same family (Pycnonotidae) as
505 *Arizelocicla nigriceps*, a species abundant in all three habitats. A similar pattern of stable
506 functional traits between birds of regenerated habitats previously disturbed by fire and those of
507 clearings and old growth forests, was reported by Ikin et al. (2019) in a temperate landscape of the
508 South West Slopes bioregion, in Australia.

509 Although the birds recorded in the assisted natural regeneration habitats were essentially a subset
510 of the birds of the primary forest, the shift towards higher mean values for traits related to the
511 body size in the former habitats contradicts what is often documented in fragmented habitats,
512 where small-bodied birds dominate the avian communities (Poulsen et al., 2011). In the absence
513 of substantial hunting of birds in the Nyungwe NP, the dominance of large-sized birds
514 corroborates the landscape texture hypothesis. This concept postulates that smaller bodied
515 organisms are more associated with landscapes with a complex texture, whilst large-bodied ones
516 are associated with simple textures (Holling, 1992; Fischer et al., 2008). The varying restoration
517 interventions create discontinuities in the landscape, which in turn generates different assemblages
518 of birds (Lindenmayer et al., 2012). The filtering of the discontinued vegetation systems along
519 avian body size traits has been documented from habitat to continental scales (Allen and Holling,
520 2008; Thibault et al., 2011; Nash et al., 2014).

521 **4.3 Efficacy of the restoration project actions in benefiting birds**

522 In comparison to natural regeneration, the present study did not find a higher impact of the
523 assisted natural regeneration intervention in terms of recovering the avian diversity. In the course
524 of 20 years, bird communities of the two regenerating habitats remained distinct and had lower
525 diversity levels relative to undisturbed primary forest. Although some trophic niche axes were
526 more associated with certain habitats, there was no proof of filtering out of specific traits by a
527 given habitat type.

528 The lack of pronounced efficacy of the assisted natural regeneration approach in recovering avian
529 species and functional diversity might be due to the early phase of regeneration process within
530 restored sites. The vegetation was characterized by a low tree diversity and dominance of pioneer
531 woody species, particularly *Macaranga kilimandscharica* and *Hagenia abyssinica*. How long it
532 may take for the restored vegetation to resemble the old growth and to regain an avian assemblage
533 similar to that of old growth remain outstanding questions. The possibility of not attaining old
534 growth levels and the development instead of a novel assemblage is another possible outcome
535 (Catterall et al., 2012). Further studies and experiments will be needed to address these questions.

536 An important factor that was not incorporated in this study, owing to a lack of fine-scale data, is
537 fire severity. Fire severity can dictate the degree of damage experienced by a habitat and thus may
538 influence the speed of recovery of the vegetation structure and composition and associated fauna
539 (Franklin et al., 2000; Roberts et al., 2020). With better fire monitoring tools being introduced in
540 the Nyungwe NP, such data will allow improved inferences to be made in the future.

541 The restoration project in the Nyungwe NP deliberately chose to rehabilitate sites deprived of all
542 trees and covered in ferns. It was hoped that with the elimination of ferns, a diversified tree cover
543 would develop, and the canopy cover of the restored nuclei would progressively shade out ferns in
544 neighbouring sites, eventually becoming a fully forested landscape supporting a range of

545 ecosystem processes (Masozera and Mulindahabi, 2007). This study confirms the validity of the
546 project's assumptions, in respect to the roles of tree species diversity in supporting a high avian
547 diversity, and fern coverage in hindering it.

548 Although tree cover can be indispensable for a high avian diversity (especially of insectivores and
549 canopy foragers) in forested habitats (Şekercioğlu et al., 2002; Ikin et al., 2019), to accommodate
550 both dense-forest interior birds and those with other habitat affinities will require the maintenance
551 of diverse habitats (Kupsch et al., 2019). As a montane ecosystem, the physiognomy of the
552 Nyungwe NP prior to burning differed from other rainforests, which are typically characterized by
553 an enclosed canopy. Nyungwe NP comprised a mosaic of forest habitats owing to the dispersal
554 barriers presented by valleys and ridges and steep cliffs. Longitudinal studies will reveal whether
555 the restored sites will maintain the variation in forest structure (e.g. canopy openness), or whether
556 further management interventions will be needed to recreate the variety of habitats.

557 **4.5 Study contribution to global restoration frameworks**

558 This study contributes to the documentation of empirical evidences of restoration activities in
559 Rwanda and similar tropical landscapes. Advancing the field of tropical forest necessitates the
560 wide sharing of steps of restoration projects, including both desired outcomes and failures (Holl,
561 2017). Such knowledge-sharing is particularly important since despite the increasing national and
562 global commitments to restore degraded forest through frameworks such as the Bonn challenge
563 and the complementary New York declaration on forests, since 2000, only 26.7 Mha of forests
564 have been reported as restored, representing just 18% of the 2020 goal (NYDF Assessment
565 Partners, 2019). Moreover, many restoration projects commence without well-defined ecological
566 goals, have conflicting end-goals, lack scientific-based guidance and monitoring, and have
567 resulted in forests providing low biodiversity and reduced ecosystem services (Li et al., 2014;
568 Jacobs et al., 2015). Countries like Rwanda have shown high willingness to restore degraded
569 forests. However, current conflicting policies in the forestry and agriculture sectors (Fagan et al.,

570 2020; Rurangwa and Whittaker, 2020), may result in forest ecosystems that do not contribute
571 substantially to global restoration goals. Studies like ours are important in documenting
572 restoration processes and can serve to guide decision-making on the conservation of intact
573 rainforest systems and future restoration management plans and actions.

Appendix 1

872 **Table A.1** Species list of bird species recorded in 100 m radius points (N=600) in Nyungwe National Park, Rwanda. Habitat preference, dietary guild,
873 foraging stratum and species loadings for Axes 1 and 2 of the RLQ ordination (Fig. 4c) are provided. The RLQ analysis involves species recorded within 20
874 m radius plots. PF: Primary forest; NR: Naturally regenerated; AR: Assisted naturally regenerated. A habitat is marked as preferred if it encompassed at least
875 50% of a species' recordings in this study. Two habitats are assigned, if they were used equally by the species, and their combined proportions constituted at
876 least 80% of all recordings. Generalist species (GEN) exhibited no preference to a particular habitat. FruiNect: Fruit/Nect (Frugivore), Invert: Invertivore;
877 VertFishScav: Vertebrate/Fish/Scavenger, Strat.Low: Lower stratum, Strat.Mid: Medium stratum, Strat.Gen: multiple strata, Omn: Omnivore. Dietary
878 information is obtained from Wilman et al. (2014). Nomenclature follows the IOC world bird list, version 8.2. Doi: 10.14344/IOC.ML.8.2.

880

881 **Table A.2** Results of analysis of similarity (ANOSIM) based on the Bray-Curtis distance for bird
 882 communities within Nyungwe NP, Rwanda. The sample statistic r ranges theoretically from -1 to +1.
 883 Values close to +1 signal a high degree of similarity between samples belonging to the same group, and
 884 thus greater dissimilarity with the compared group.

885

Habitats (sample size)			
1st Group	2nd Group	P Value	Sample Stat. (r)
PF (20)	MNR (14)	0.001	0.435
PF (20)	YNR (6)	0.001	0.681
PF (20)	MAR (10)	0.001	0.422
PF (20)	YAR (10)	0.001	0.522
MNR (14)	YNR (6)	0.136	0.137
MNR (14)	MAR (10)	0.396	0.011
MNR (14)	YAR (10)	0.023	0.152
YNR (6)	MAR (10)	0.004	0.389
YNR (6)	YAR (10)	0.001	0.476
MAR (10)	YAR (10)	0.004	0.235

886 Note. PF: Primary forest, MNR: Mid-age naturally regenerated sites, YNR: young naturally regenerated
 887 sites, MAR: Mid-aged assisted naturally regenerated sites, YAR: young assisted naturally regenerated
 888 sites.

889

890 **Table A.3** Mean and standard deviation of elevation and vegetation attributes of study area
 891 samples averaged per habitat type and across two sampling seasons (2017/2019) within Nyungwe
 892 NP, Rwanda. The attributes were recorded in 20m radius plots. 100 plots were sampled in each
 893 habitat. 5 adjacent points were aggregated to form a sample.

894

Habitat	Elevation (m)	Canopy cover (%)	Ferns (%)	Tree diversity	DBH (cm)	Canopy height (m)
AR	2503.6±67	64.4±6	29.7±11	2.3±1	22.8±4	13.6±2
NR	2374.8± 186	56.3±13	42.4±22	5.3±3	27.5±9	11.4±3
PF	2174.1±305	62±7	1.5±3	10.2±3	52.1±14	22±4

895 DBH = Diameter at breast height measured at 1.3 m.

896

897

898 **Table A.4** The relationship between vegetation attributes for sample plots (n= 20 per habitat) within
 899 primary forest, naturally regenerated forest and restored forest in Nyungwe NP, Rwanda. The average
 900 and importance of the models within $\Delta\text{QAIC}_c < 2$ is given. Importance values close to one indicate a
 901 stronger effect whilst those close to 0 indicate weaker effects.

902
 903

Abundance								
	Cnp.cover	Ferns	Tree.div	adjR ²	logLik	QAICc	delta	weight
1			0.17	0.37	-216.58	159.13	0.00	0.27
2	0.08		0.16	0.42	-214.21	159.75	0.63	0.20
3		-0.09	0.11	0.41	-214.56	160.00	0.87	0.18
4		-0.17		0.34	-217.85	160.02	0.90	0.18
Average	0.08	-0.13	0.15					
Importance	0.37	0.51	0.74					

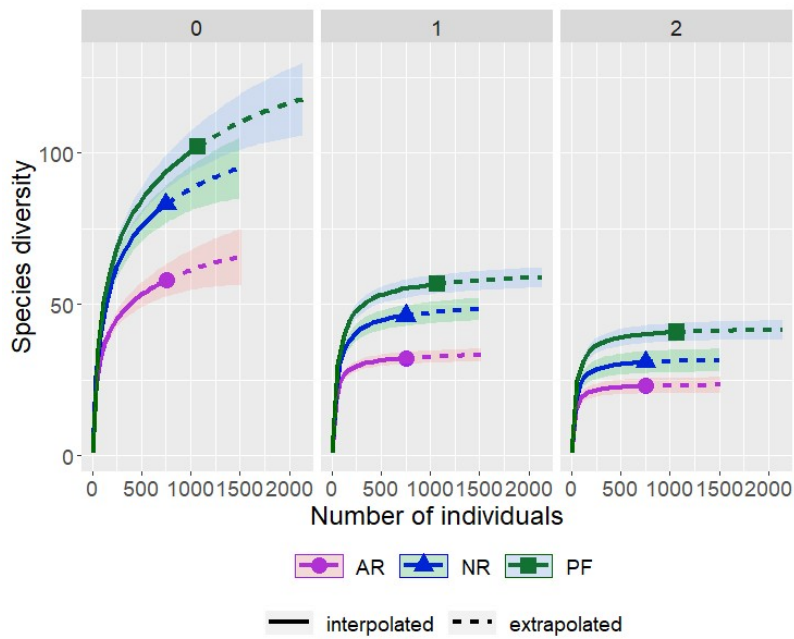

904
 905 Note: Cnp.cover = Canopy cover, Ferns = cover of ferns, Tree.div =Tree species diversity, measured as
 906 exponential of Shannon entropy. QAICc, is a modified AICc (Akaike information Criterion for small
 907 samples) for models with overdispersion.

908
 909

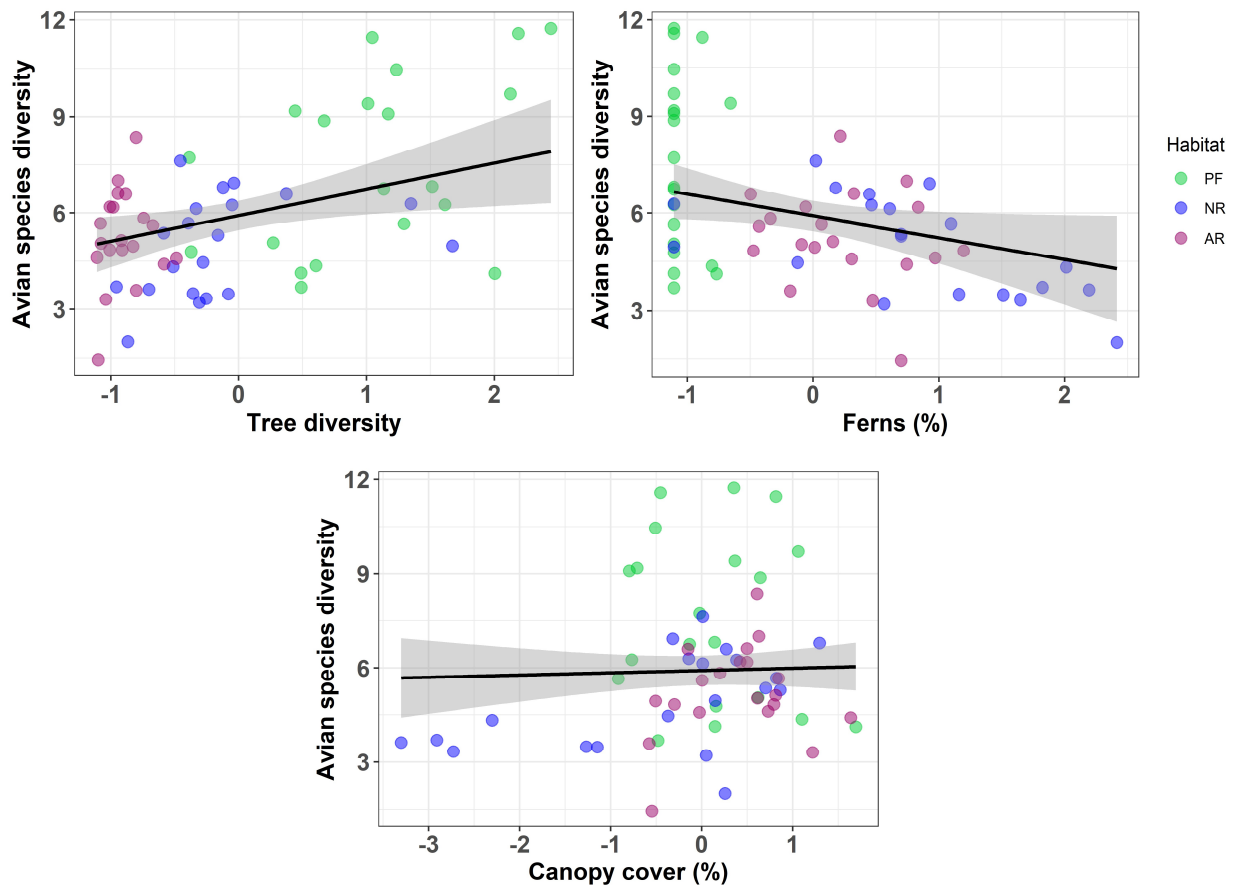

910
 911 **Figure A.1** Correlation plot of vegetation attributes and corresponding Pearson R correlation coefficients
 912 for study samples (N= 60) within naturally regenerated, assisted-naturally regenerated and primary forest
 913 within Nyungwe NP, Rwanda. A sample comprised 5 adjacent plots. Each attribute was measured twice: in
 914 the wet season, and the dry season of 2017/2018. DBH and Canopy height (Cnp.ht) were excluded from
 915 further analysis.

916
 917
 918
 919
 920

921
 922 **Figure A.2** Species rarefaction curves computed for each habitat to evaluate the exhaustiveness of
 923 sampling efforts. The species diversity of birds is calculated for the Hill numbers, where $q=0$ is based on
 924 the Chao 1 species richness estimator, $q=1$: the Shannon entropy index, and $q=2$: the Simpson diversity
 925 index. The shaded areas represent 95% Confidence intervals. The graph and estimates were obtained using
 926 the R package “iNext” (Hsieh et al., 2016).

927
 928
 929 **Figure A.3** Relationships between avian species diversity (exponential of Shannon entropy), functional
 930 diversity, and vegetation attributes of study samples (N=20 per habitat) in the primary forest (PF),
 931 Naturally regenerated sites (NR), and assisted naturally regenerating sites within Nyungwe National Park,
 932 Rwanda. Results were obtained from a multiple linear regression analysis. Attributes were first
 933 standardized to mean of 0 and standard deviation of 1. The grey band represents $\pm 95\%$ confidence
 934 interval. Further details are presented in Table 2.

935

936
