## 49   **Abstract**

50       Palaeobotany and palynology are the main direct sources of evidence for studying  
51   vegetation diversity dynamics through geological time. However, plant fossil diversity is  
52   affected by various factors other than vegetation diversity, which need to be taken into  
53   account in such studies. The use of fossil-taxa will potentially inflate perceived plant  
54   diversities, requiring taxonomic lists to be normalised. Autochthonous floras provide the  
55   most direct evidence of vegetation diversity but these are rare; most plant beds are  
56   allochthonous with plant remains that have been subjected to varying levels of fragmentation,  
57   transportation and time averaging. Local-scale vegetation diversity is especially difficult to  
58   determine from the fossil record, even with rigorous sampling protocols and detailed  
59   sedimentological analysis. Landscape-scale and regional-scale vegetation diversities are more  
60   reliably determined but usually at the rank of family. Macrofossil and palynological data tend  
61   to reveal evidence of different aspects of plant diversity, and the best results are obtained if  
62   the two diversity signals are integrated. Despite the inherent difficulties, the plant fossil  
63   record provides clear evidence of the dynamic history of vegetation through geological times,  
64   including the effects of major processes such as climate changes and mass extinctions.

## 1 Introduction

Vegetation has played a central role in the evolution of the Earth's biosphere, atmosphere and landscape (Beerling 2007; Davies and Gibling 2010; Wellman 2010; Willis and McElwain 2013); whilst it is possible to envisage a world having evolved with plants but no animals, a world of animals without plants could not function. The raised public awareness of the important ecosystem services provided by vegetation, including carbon capture to help mitigate climate change, providing the foundations of all terrestrial trophic systems, and the psychological benefits it brings to mankind, has resulted in a global research programme on today's plant diversity and ecology (Antonelli et al. 2020). However, this only provides a snapshot of a continuous ecological and evolutionary play that has taken place through some 500 million years of "Deep Time". To appreciate properly the significance of events such as the current biodiversity crisis ("the 6<sup>th</sup> mass extinction") and to anticipate potential outcomes, it is vital that we understand this history of vegetation evolution.

Research into vegetation history started over two centuries ago (for summary see Andrews 1980) but with the primary focus on plant phylogeny (Taylor et al. 2009; Cleal and Thomas 2019). In recent years, interest in the study of plant fossil diversity has grown (as summarised by Wing and DiMichele 1992; Willis and McElwain 2013) but investigating it remains challenging (Wing and DiMichele 1995).

This is one of two papers arising from a workshop on past plant diversity entitled *Tracking changes in plant diversity over the last 400 million years*, which brought together specialists on diversity studies in fossil floras ranging in age from Devonian to Quaternary . The aim was to explore the different analytical methodologies and interpretative approaches used to investigate Phanerozoic plant diversity dynamics. The present contribution addresses what exactly we mean by biodiversity and to what extent can we extract biodiversity patterns from the plant fossil record. We will attempt to look at the relevant issues surrounding both

plant macrofossils (i.e. fossils that can normally be seen with the naked eye, including compressions / impressions / adpressions, casts / moulds and anatomically preserved fossils – see Cleal and Thomas 2019) and microfossils (pollen, spores and phytoliths). The issues surrounding sampling and analytical methods used will be discussed in our second paper (in preparation).

## **2 What is biodiversity?**

In biology, biodiversity is sometimes used to refer to functional diversity (the range of traits in an assemblage) or phylogenetic diversity (the evolutionary breadth of an assemblage) (Dornelas et al. 2012; Vellend et al. 2011, 2017). Palaeobotanists also sometimes investigate trait diversity, such as the use of leaf physiognomy for estimating past climatic temperatures (Wolfe 1993; Glasspool et al 2004). But diversity analyses of the plant fossil record tend to be overwhelmingly of taxonomic diversity, and it is on this that we will focus here.

Taxonomic diversity in ecological studies consists of two factors: taxonomic richness and taxonomic evenness (Tuomisto 2012). Taxonomic richness (the number of taxa present) might be expected to be relatively easy to measure in both modern-day habitats and the fossil record; Magurran (2004) has suggested that this alone can be a sensitive indicator of ecological change. However, total richness can be difficult to determine if there are rare species present, as these may be missed in surveys. A far more nuanced understanding of the functioning of a flora will be obtained by determining its taxonomic evenness using measurements such as Simpson's Index (e.g. Lande 1996; Veech et al. 2002) but this is only really meaningful if it is reflecting the relative numbers of the organisms present. Variations in the productivity of pollen, foliage and seeds between different plant parts (Fig. 1) mean that taxonomic evenness of fossil-taxa in a fossil flora will bear little or no relationship to the taxonomic evenness of the original vegetation. The situation is particularly complex with

foliage, especially in pre-Cenozoic floras where the leaves are often compound structures that fragmented in different ways during abscission, transportation and preservation. Taxonomic evenness of a fossil flora may therefore be strongly influenced by taphonomy and how the plants fragmented post-mortem; although such data may provide some evidence as to relative biomass allocation within the vegetation (e.g. Baker and DiMichele 1997), its value for determining taxonomic evenness is limited.

Scale will clearly be critical in any diversity study, whether palaeontological or biological (Bennington et al. 2009). R.H. Whittaker (1960) developed the most frequently used concepts of taxonomic diversity for extant biotas, broadly recognised as  $\alpha$ -diversity (diversity in particular habitats) and  $\beta$ -diversity (diversity between habitats within a landscape); these were then integrated to provide a  $\gamma$ -diversity (overall diversity within the landscape). R.H. Whittaker (1977) later extended this scheme to include  $\delta$ -diversity (diversity between landscapes in a biogeographical province) and  $\epsilon$ -diversity (overall diversity within that province). However, R.H. Whittaker's (1960) terms were intentionally rather vague and as a consequence have been used by different scientists in different ways (see Swingland 2001; Magurran 2004; Hamilton 2005 for reviews).

In an attempt to introduce taxonomic diversity concepts that more realistically reflect the plant fossil record, Cleal et al. (2012) adopted a more flexible approach similar to those used by R.J. Whittaker et al. (2001); see also Birks et al. (2016a,b) (Fig. 2):

(1) Local-scale diversity: the diversity of plant fossils observed in a single locality and which probably reflects plant diversity within c. 1000 m<sup>2</sup> (c. 30 m x 30 m). In a palynological context, it might more realistically refer to vegetation within up to 1 km<sup>2</sup>. This will broadly equate to the  $\alpha$ -diversity of the parent vegetation.

(2) Landscape-scale diversity: the diversity of plant fossils observed within a typical depositional basin and which probably reflects plant diversity within up to c.  $10^5$  km<sup>2</sup> (c. 300 km x 300 km) This will broadly equate to the  $\gamma$ -diversity of the parent vegetation.

(3) Regional-scale diversity: the diversity of plant fossils observed within a palaeofloristic province and probably reflects plant diversity within more than  $10^5$  km<sup>2</sup>. This will broadly equate to the  $\epsilon$ -diversity of the parent vegetation.

It is important to remember that the diversities observed in the fossil record (both macrofloral and palynological) represent the diversities of the fossils, and only partially reflect the diversities of the parent vegetation (Gastaldo 1992; Birks et al. 2016). Some of the resulting issues will be discussed later in this paper (Section 4).

### **3 Taxonomic problems**

#### *3.1 Macrofossil taxonomy*

The concept of biodiversity is inevitably tied to taxonomy (Khuroo et al. 2007). In neobotany this is relatively straightforward as the taxonomy is based on whole-organism taxa in which their lifecycles and development can be observed. There will always be disagreements among botanists as to whether a particular genus of plants contains one or more species, or a group of species belong to one or more genera, but at least botanists have whole organisms against which to test their taxonomies.

With Cenozoic macrofloras (including Quaternary) it is often still possible to work with whole-plant taxa (e.g. Huang et al. 2016) but the situation is more difficult with older floras where palaeobotanists are dealing with extinct groups. Only rarely are completely reconstructed organisms available to work with; even if a whole, articulated plant is preserved (e.g. the early seed plant *Elkinsia* – Fig. 3) anatomical details are never completely preserved. Palaeobotanists working on these stratigraphically older floras therefore use a

different taxonomic approach. Although this has changed in detail over the years (Cleal and Thomas 2010), the underlying principle has in effect remained the same since the time of Sternberg (1820) and Brongniart (1822): different parts of the plant are classified and named separately as fossil-taxa (Turland et al. 2018, Art. 1.2). Mostly these are fossil-species and fossil-genera, although in principle they can be of any rank (see Cleal and Shute 2012 for an example of using fossil-families).

Exactly how a fossil-taxon is defined is a subjective matter and is not covered by the regulations in the *International Code of Nomenclature* (Turland et al. 2018), but this is no different from neobotany. Because of the constraints of the fossil record (e.g. the inability to test hypotheses relating to reproductive isolation or molecular phylogenetics) fossil-taxa have to be defined purely on morphological and/or anatomical criteria. Bateman and Hilton (2009, p. 1256) recommended that each fossil-taxon "...must consistently possess at least one morphological feature that it shares with no other [taxon]" (their autaposppecies concept) and should not take into account geographical or stratigraphical criteria. Whether this latter point is always supportable is perhaps a moot point: for instance, is it helpful to place leaves of Permian gigantopterids and of Cenozoic angiosperms in the same fossil-genus simply because they have the same, diagnostic characters (Fig. 3)? However, since most diversity studies at the rank of species or genus tend not to be making comparisons over such long time-scales, this is probably not a significant problem here.

The problem with using fossil-taxa for diversity studies is that a simple summation of the names listed in published taxonomic lists will both significantly overestimate the number of biological species represented, and distort the relative representation of the different plant groups present (Cleal et al. 2012). For instance, in Carboniferous arborescent lycopsids, a single biological species may be represented by up to six separate compression fossil-species, whereas sphenopsids in the same flora may only have four fossil-species (Fig. 4; Table 1). An

added complication is that the fossil-taxa of the different plant parts are probably indicative of different taxonomic ranks of the original organism: for instance, *Stigmaria ficoides* (Sternberg) Brongniart is a fossil-species of phylogenetically conservative lycopsid rootstock that effectively cannot be distinguished across many members of the order, whereas the stems and cones have more sophisticated combinations of derived evolutionary characters and so their fossil-species probably correlate better with the biological species of the organisms.

One solution would be only to study whole reconstructed plants (DiMichele and Gastaldo 2008). This is feasible when dealing with higher-ranked taxa such as families (e.g. Anderson et al. 2007) but at the present time there are too few reconstructions to provide meaningful diversity data at the rank of species or genus. A solution is to normalise the dataset by identifying, for each plant group, the plant part whose fossil-taxonomy is most likely to reflect the original, whole-organism taxonomy (e.g. Hilton and Cleal 2007; Cleal et al. 2012). For instance, the study of the late Carboniferous tropical swamps focussed mainly on foliage taxa, except with the arborescent lycophytes for which the outer periderm layer (“bark”) of their trunks was used (Table 1; Cleal 2005, 2007, 2008a). Leaf morphotypes have also been successfully used in this way with Cretaceous and Palaeogene angiosperms (e.g. Johnson 2002). Although these vegetative fossil-taxa may not provide the best evidence of phylogenetic relationships (reproductive structures would probably be better for this – e.g. Meyen 1984), they are probably providing a robust reflection of the plant species diversity (Cleal et al. 2012). This will inevitably be imperfect; for instance, cuticle studies of Carboniferous *Cordaites* and *Selaginella* foliage have shown that diversities will be significantly underestimated if the identifications are based purely on morphological data (e.g. Thomas 2005; Šimůnek 2007). There is no easy solution to this issue and simply has to be accepted in such diversity studies.

The situation is further complicated in that the same plant preserved in different ways (e.g. petrifications and compressions) will be recorded as different fossil-taxa (Galtier 1986; Bateman and DiMichele 1992; Bateman et al. 1992; Bateman and Hilton 2009; Thomas and Cleal 2020). It is critical, therefore, to ensure that assessments of diversity do not duplicate fossil-taxa in the same assemblage or locality that are preserved in different ways; for instance, if an assemblage should include lycopsid cones as both compressions and permineralisations, the taxonomic list should be normalized so that diversity is not artificially inflated by “double counting”.

### 3.2 *Palynotaxa*

Palynological studies on Quaternary floras tend to use whole-plant taxa, based on morphological comparisons with pollen that have been extracted from living plants. It is sometimes possible to distinguish pollen from closely related plant species based purely on morphology but often palynological studies tend to focus mainly on differentiating plants at the generic rank. Attempts have been made to use DNA barcoding to improve the taxonomic resolution in Quaternary studies (e.g. Seppä and Bennett 2003); for instance, Petit et al. (2002) demonstrated that the modern genetic diversity of oak is consistent with the pollen evidence in a study of post-glacial oak migration. However, most Quaternary palynological studies remain essentially morphology-based.

With older floras, the known relationship between the pollen / spores and their parent plants is less certain and so palynologists have developed separate taxonomic schemes (Chaloner 1999). Some proposed taxonomies are completely artificial with the taxa defined purely on morphological criteria with a non-Linnaean nomenclature, such as used in many oil-company palynological databases and in the Biorecords methodology of Hughes (1963) (see Traverse, 2007 for a review). Other taxonomies use a Linnaean-style nomenclature but with taxa that were still essentially morphological (e.g. Potonié 1956, 1958, 1960) and it is

238 this approach which is most usually widely used today in pre-Neogene studies (e.g. Jasper et  
239 al. 2010; Stolle 2007, 2012, 2016; Hochuli et al. 2016).

240 Because the botanical affinities of many pre-Neogene palynotaxa are uncertain, it can be  
241 difficult to translate observed palynodiversity trends into floristic trends. Thomas (1987) and  
242 Mander and Punyasena (2014) suggested that the situation could be improved by revising the  
243 diagnoses of palynotaxa based on evidence from in situ palynomorphs in fructifications, data  
244 which is now being increasingly collated (e.g. Balme 1995; Bek 2017). Experience with  
245 Palaeogene and Neogene pollen and spores has also shown that a combination of light  
246 microscopy and scanning electron microscopy based on individual grains (Ferguson et al.  
247 2007), although very time consuming, can help to improve their assignment to a particular  
248 plant genus or family, or perhaps even to map it into an established framework represented by  
249 one or more phylogenetic trees. (e.g. Grímsson et al. 2011a,b, 2015a,b). Chemical analysis  
250 such as using FTIR (Fourier Transform Infra-Red) and fluorescence spectroscopy can also be  
251 helpful in determining affinities of particular palynomorphs (e.g. Mitumoto et al. 2009;  
252 Steemans et al. 2010; Urban et al. 2010). This approach has shown that more traditional  
253 approaches utilizing only light microscopy tend to underestimate the number of taxa present  
254 in a palynoflora (Hofmann and Gregor 2018).

255 An added complication is the variation in morphology of pollen and spores during  
256 maturation, as shown for instance in the fern *Weichselia reticulata* (Stokes and Webb)  
257 Fontaine (Fig. 5). This is not an issue in most diversity studies on dispersed palynofloras, as  
258 plants do not normally release their pollen or spores before they are fully mature. However, if  
259 a plant has been subjected to trauma such as a storm, immature pollen and spores may be  
260 prematurely released and preserved, and this could inflate the diversity of a palynofloras.  
261 Although labour intensive, it is possible to determine whether different morphologies

represent different states of maturity or just variability of miospore forms within a species using sporoderm ultrastructure analysis (e.g. Zavialova et al. 2010).

Because of the problems of classifying stratigraphically older palynotaxa a number of purely morphological suprageneric classifications have been developed (see Traverse 2007 for a review). Especially in Palaeozoic palynofloras, a nested hierarchy of morphological groups (anteturma, turma, subturma, etc.) developed by Potonié (1934) is still widely used, and provides a useful framework for descriptive studies. However, as these groups are strictly morphological, they rarely relate to botanical suprageneric groups and so are of limited use in diversity studies.

### 3.3 Taxonomic rank

Because of the problem of relating pollen and spores to particular plant species, using palynology for species diversity studies can be difficult (Mander and Punyasena 2014); even in the Quaternary where the relationship between pollen and parent plants is better-known, most palynological diversity studies tend to be at the rank of genus or even family (Giesecke et al. 2014). Such studies have nevertheless provided valuable evidence of vegetation dynamics especially at the landscape-scale (Section 5.2).

Local- and landscape-scale plant macrofossil diversity studies tend to be based on normalised inventories of fossil-species or possibly fossil-genera (Section 3.1). However, species are currently impractical when dealing with diversity changes at regional- or global-scales, and over longer time-scales, as the datasets become too large to collate and check objectively by any individual scientist or team. Even where a large amount of species data has been historically accumulated, such as for the Pennsylvanian Subsystem (see comments by Pfefferkorn et al. 2017), there have been few attempts to collate them coherently and critically. Where such collations have been attempted (e.g. Niklas et al. 1980; Lidgard and Crane 1990), methodological and sampling issues occurred (see comments by Niklas and

Tiffney 2010; Cascales-Miñana et al. 2013). Moreover, these early collations were not published and so cannot be subjected to subsequent critical taxonomic re-assessment, making the robustness of the resulting analyses difficult to judge.

The situation may potentially improve with the development of large-scale computer databases of fossil occurrences, such as those for Cenozoic angiosperms (Xing et al. 2016; Williams et al. 2018). Palaeobotanical data have also been included in the Paleobiology Database (Alroy 2003) although its coverage for plant fossils remains uneven, and is far below that in other groups such as fossil vertebrates. Various numerical approaches have been investigated that aim to overcome the issues of incomplete sampling of such databases (e.g. Silvestro et al. 2015; Beri et al. 2020) but the intractable problem remains of verifying the taxonomic robustness of the data; if the data cannot be trusted, how can the results of any analysis? This is an area where palaeobotany needs to improve in order to catch up with other fossil groups and make sustained impact in analytical methodologies.

In the absence of usable databases, the solution adopted in many regional- and global-scale macrofloral diversity studies is to analyse changes at the rank of family. Family is the lowest rank of fossil-taxa based almost exclusively on whole organisms and so potentially the dynamics of the fossil-families should be comparable with those of the original parent families. A number of global collations of plant fossil-family distributions through geological time are available (e.g. Harland 1967; Benton 1993; Collinson 1996; Anderson et al. 2007) and they include the evidence on which the records were based and so can be subjected to later critical assessment and potential revision (Cascales-Miñana and Cleal 2014).

But how closely do family dynamics mirror diversity dynamics at lower taxonomic ranks? Analyses on modern-day tropical forests suggest that family and species diversity patterns are broadly similar (e.g. Enquist et al. 2002; Jantz et al. 2014) especially if the data are log transformed to reduce the effect of dominant families (La Torre et al. 2007); see also

comments by Giesecke et al. (2019) and Reitalu et al. (2019) on Holocene data from Europe. However, this does not take into account the taphonomic filter that fossil floras have been subjected to; many Palaeozoic and Mesozoic plant fossils cannot be assigned to families due to missing, or difficult to deduce, features of reproductive organs or cauline anatomy, suggesting the fossil record of families is incomplete. On the other hand, regional- and global-scale vegetation analyses (e.g. Cascales-Minana et al. 2013) may benefit from using family data because they may help smooth out some of the sampling problems encountered in such large-scale analyses. This is clearly a subject that needs further investigation.

#### **4 Representativeness of data**

There have been many studies looking at the effects of representativeness on diversity studies in the macrofossil record, such as the effects of sampling and taphonomy, but mainly dealing with faunas, notably marine invertebrates (e.g. Kowalewski et al. 2006). However, the issues surrounding such faunal studies are fundamentally different from those facing palaeobotanists and palynologists, as most palaeozoologists have the luxury of dealing with the remains of whole organisms (or at least their hard-parts, such as shells or exoskeletons); even vertebrate palaeozoologists tend to deal with whole-organism taxa. Palaeobotanists and palynologists, in contrast, deal almost exclusively with allochthonous and fragmentary remains; there are exceptions, as we will discuss, but these tend to be rare and scattered, and difficult to use in diversity studies. This means that diversity studies on the plant fossil record are addressing quite different questions to those being usually asked by palaeozoologists: palaeobotanists and palynologists tend to be looking at broad composition of vegetation either in terms of taxa or biomass rather than looking at changing community structure in terms of individual organisms (e.g. Bambach 1977).

#### 4.1 Macrofloral data

Autochthonous floras (sometimes misleadingly referred to as “Lagerstätten”) provide the most reliable data on original plant diversity, especially at a local-scale, but these are rare. One of the best documented is the Devonian Rhynie Chert (e.g. Edwards et al. 2018; Garwood et al. 2019; Strullu-Derrien et al. 2019) where an in situ and almost complete terrestrial biota is preserved including relatively small, herbaceous plants. Autochthonous fossil floras with larger, woody plants are much rarer. There are exceptions, such as the Palaeozoic swamp forests that were rapidly covered by volcanic ash (Sections 5.1, 5.2); but more usually, the so-called T<sup>0</sup> fossil or submerged forests (DiMichele and Falcon-Lang 2011) are only partly autochthonous. They form where an area of forests has been engulfed by a flood of sediment and casts of the stumps have been preserved in situ (e.g. Fig. 6; for other examples see Heyworth and Kidson 1982; Francis 1983; Gastaldo 1985; Pole 2001; Calder et al. 2006; Wagner and Diez 2007; Moir et al. 2010; Stein et al. 2012; Berry and Marshall 2015; Thomas and Seyfullah 2015; Falcon-Lang et al. 2016), but most of the herbaceous ground-cover and liana species have been winnowed-out (Thomas 2014). Other types of “fossil forests” consist of petrified logs preserved as log-jams that have been subject to varying degrees of transportation (e.g. Falcon-Lang and Bashforth 2005) and thus also difficult to use for diversity studies.

More typically, plant beds occur in fluvio-lacustrine deposits, where disarticulated plant remains have accumulated after varying degrees of transportation either by wind or water (Burnham 1989; Gastaldo et al. 1995; Kędzior and Popa 2013, 2018; Thomas and Cleal 2015). This is in marked contrast to many fossil faunal communities, which tend to be much less prone to transportation (Kidwell and Holland 2002). Many attempts at palaeoecological studies on such plant beds have documented in great detail the sedimentological context where the fossils occur (e.g. Scott 1978, 1989; Gomez et al. 2012; Kędzior and Popa 2013,

2018). Detailed, three-dimensional sampling such as in underground coal mines along directional and transversal galleries and in coal extraction chambers in particular can provide valuable data (e.g. Gastaldo 1985; DiMichele and Nelson 1989; Popa 1998, 2011, 2014; DiMichele et al. 2007, 2017; Barbacka et al. 2016).

However, the plant remains will have been transported over varying distances, making it difficult to translate the observed distribution of the fossils into original plant diversity (Gastaldo 1992). In a few cases, the fossils in such plant beds seem to have been subjected to only limited transport, such as where a river-bank bank has collapsed and the plant remains have become entombed in a crevasse-splay (e.g. Cleal and Thomas 1988; Laveine and Belhis 2007). More usually, however, the plant remains are at least partly allochthonous. Actualistic studies suggest they will include only a variable representation of the immediately local vegetation (e.g. Burnham 1989, 1994) mixed with remains derived from riparian vegetation growing some distance upstream (Spicer 1980, 1981; Scheihing and Pfefferkorn 1984; Ferguson 1985; Gastaldo et al. 1987; Gastaldo and Huc 1992).

By carefully documenting the co-occurrence of species within individual beds, the composition of individual plant communities can be estimated (e.g. Procter 1994; Bashforth et al. 2010, 2011; Barbacka 2012; Barbacka et al. 2016; Thomas et al. 2020). However, locating those communities in the original vegetation / habitat matrix requires a detailed understanding of the sedimentology of the deposits (DiMichele and Gastaldo 2008; Reitalu et al. 2014) and is at best difficult. Moreover, taphonomic factors may distort the observed diversities. Variations in edaphic conditions can cause variable post-mortem decay of the plant tissue (Gastaldo 1992; Gastaldo and Demko 2011). It has been suggested that differential decay of plant groups may distort the species composition (Scott 1979; Wing and DiMichele 1995) although the effect of this may have been exaggerated (Locatelli et al. 2016; Tomescu et al. 2018). More significant may be differential sorting of the plant remains during

transportation: smaller plant fragments will tend to travel further and softer, heavier plant fragments sink more quickly (e.g. Steart et al. 2002). Some element of time-averaging may even occur within a single plant bed depending on depositional rates of the sediment.

Plant remains preserved in shallow marine deposits are usually fragmentary and not concentrated into distinct plant beds, although there can be exceptions caused by storm surges (e.g. Kustatscher et al. 2010). Fossil floras preserved in marine deposits can include the remains of coastal vegetation such as mangroves (e.g. Collinson 1993). During late Permian times, climatic conditions were unfavourable for plant growth in continental Europe and so vegetation tended to be concentrated in coastal areas; remains of this vegetation has been found in shallow marine deposits, preserved particularly during transgression phases (Kustatscher et al. 2017).

Some plant macrofossils preserved in marine strata have been interpreted as plant remains washed down from hinterland vegetation (e.g. Rothwell et al. 1996; Rice et al. 1996; Cleal and Rees 2003) and are notably different from what is seen in fluvio-lacustrine plant beds. “Exotic”, extra-basinal plant remains have also sometimes been reported from fluvio-lacustrine plant beds (e.g. Cleal and Thomas 2004; Uhl 2006; Opluštil et al. 2007). Generally, however, plants growing in places away from rivers or lakes are poorly represented as macrofossils. For instance, grasses, which are obviously major components of terrestrial vegetation today, have a very poor macrofossil record and much of what we know of their evolution is based on palynology (Section 4.2) or dispersed phytoliths derived from their leaves (e.g. Piperno and Pearsall 1998; Strömberg 2004, 2011).

Fossil floras can also occur in maar lake deposits (e.g. the Messel World Heritage Site – Collinson et al. 2012). Such lakes are caused by phreatomagmatic explosions resulting from the interaction of erupting magma and water, and can occur almost anywhere within a landscape and thus may be surrounded by a different type of vegetation to that growing

adjacent to lakes formed in fluvio-lacustrine settings. For instance, the late Oligocene Norken fluvio-lacustrine deposits contain predominantly remains of riparian and swamp vegetation (Uhl et al. 2018) but these are almost totally absent from the nearby, almost contemporary Enspel maar lake deposits (Köhler and Uhl 2014). Plant remains in such lakes also experience less hydro-mechanical stress due to water transport and so can preserve delicate plant structure such as flowers (e.g. Uhl 2015).

#### 4.2 *Palynological data*

Palynology has been widely used for Quaternary landscape-scale diversity studies (Giesecke et al. 2014); but translating the data into vegetation patterns can be problematic because of significant variation in pollen productivity from year to year (Andersen 1970; Sugita 1993; Hicks 1985; Barnekow et al. 2007; Pidek et al. 2010; Giesecke et al. 2014). However, this is partly mitigated by most sediment samples representing several years; for example, in the Lake Sapanca sequence (N-W Turkey) sub-annual samples taken at a 5 mm resolution revealed no seasonality in the palynology signal, probably due to bioturbation of the lake sediment (Leroy et al. 2009). On the other hand, in the alternating black and white sediment layers of the Dead Sea (López-Merino et al. 2016), the seasonality of the pollen production was used to determine if the lamina couplets were varves or a laminated sediment.

Another problem is the great variation in pollen productivity between different plant species. Current evidence for northern and temperate latitudes suggests that Quaternary palynological data are particularly robust for most trees (with a few notable exceptions such as *Larix*) and wind-pollinated taxa, and provide a good measure of broad-scale plant richness over several thousands of kilometres (Reitalu et al. 2019); this is less so for tropical environments due to the higher number of insect-pollinated plants. Among herbs, the Poaceae are the most abundant wind-pollinated plants, and their pollen can be widely dispersed. However, the source of Poaceae and Cyperaceae pollen can be difficult to elucidate because

these species occur in a wide range of plant communities. It can also be impossible to identify their pollen to species level other than in cultivated cereals (Pardoe 2001; Sjögren et al. 2015), although phytoliths can be of help here (see below). Most other herbs tend to be under represented in pollen spectra (Leroy and Roiron 1996) as the pollen are dispersed by other vectors and so are not so abundantly produced; they also often have a lower preservation potential. There have been relatively few studies of the representation of herbs in pollen assemblages (Pardoe 2001; Bunting et al. 2016) but the presence of so called “indicator taxa” in pollen samples can give strong evidence that such plants were growing locally (Pardoe 1996, 2001, 2006). Data can also be supplemented by evidence from in situ pollen from flowers (e.g. Herendeen et al. 1994) and in exceptional cases from fossils of pollinating animals (e.g. Grímsson et al. 2017).

Recent initiatives such as the Pollen Monitoring Programme (PMP) are now helping us gain a greater understanding of the relationship between pollen, vegetation and environmental variables. The PMP has been instrumental in the publication of several decades-long records from across Europe (Hicks et al. 1996; Giesecke et al. 2010). The PMP has addressed a variety of problems including the representation of individual taxa (Hicks et al. 1994; Hicks, 2001, Ertl et al 2012; Pidek et al. 2010), the representation of plant communities (van der Knaap et al. 2001; Pidek 2004; Gerasimidis et al. 2006), and the influence of sampling medium on palynological diversity (Pardoe et al. 2010; Litsitsyna et al. 2012).

Although not strictly palynological, phytoliths are another type of plant microfossils that provide valuable evidence of terrestrial vegetation (Strömberg et al. 2018). There can be taphonomic issues due to silica dissolution (Cabanès and Shahack-Gross 2015) but they are nevertheless essential indicators of grass diversity in Cenozoic vegetation, which are usually poorly represented as pollen and macrofossils (Piperno and Pearsall 1998; Piperno 2002;

Strömberg 2004, 2011; Rashid et al. 2019). There are also records of pre-Cenozoic phytoliths (e.g. Carter 1999) but their affinities remain uncertain.

In principle, palynodata can be corrected using R-coefficients (sensu Davis 1963) representing the ratio between the observed pollen abundances and the abundance of plants in the parent vegetation. R-coefficients can be estimated for Quaternary data based on actualistic comparisons between surface pollen data and field vegetation surveys (although even here problems may occur because of some of the mathematical assumption involved – Parsons and Prentice 1981). Such an approach is more difficult with tests on the robustness of pre-Quaternary palynodata as often no independent measure of vegetation composition can be used to calculate the R-coefficients. Nevertheless, it has been attempted with the late Carboniferous swamps where available autochthonous macrofloras allow the coefficients to be estimated (Willard 1993; Opluštil et al. 2009). Palynofacies signals can also help in determining the robustness of palynological data by indicating the depositional and palaeoenvironmental situation of the studied strata (e.g. Stolle et al. 2012, pl. 1, fig. 2).

#### 4.3 Pollen and macrofossil data compared

When diversity data from the macrofloral and palynological records are compared (e.g. Leroy and Roiron 1996; Dimitrova et al. 2005; Birks and Bjune 2010; Xiong et al. 2013; Bjune 2014; Looy et al. 2014; DiMichele et al. 2018) rather different signals are often revealed both in the plant groups represented and the relative proportions of those plant groups (Fig. 7). The macrofloral record is regarded as giving a more detailed picture of plant species richness, especially at a local-scale (Birks and Birks 1980). However, this tends to represent only a fairly narrow band of habitats, and the much smaller sample sizes usually available compared with palynology will often be insufficient to capture diversity patterns. Palynology, in contrast, will give a better understanding of vegetation patterns across a wider range of habitats and at a landscape-scale (Dimitrova et al. 2010; Costamagna et al. 2018).

Because palynological samples may contain palynomorphs from different habitats, it can be difficult to determine the local-scale vegetation patterns within individual habitats; it may also help explain why palynospectra tend to be more diverse than the macrofloras found in the same bed (e.g. Dimitrova et al. 2005). However, as our understanding of the natural affinities of many palynotaxa is improving, palynology is proving increasingly refined evidence of landscape-scale vegetation diversities (Section 5.2). It is evident that one data source is not better than the other for diversity studies: rather, that palaeobotany and palynology are complementary, and are best investigated in tandem (Birks 2000; Kustatscher et al. 2010; Reitalu et al. 2014; Costamagna et al. 2018).

## **5 Diversity studies**

It is beyond the scope of this paper to review all examples of palaeobotanical and palynological diversity studies; the following discussion aims merely to illustrate some of the types of analyses that have been attempted.

### *5.1 Local-scale diversity*

Most allochthonous fossil macrofloras tend to reflect local-scale plant diversity (Cleal et al. 2012). However, the complexity of the sedimentary systems in which they usually occur (Section 3.1) means that the diversity of each individual bed needs to be analysed separately as each flush of sediment is likely to have remains from a different set of plant communities. Even if the plant beds are rigorously sampled (e.g. Scott 1978, 1979), a detailed understanding of the sedimentology is required before it is possible to unscramble the local-scale plant diversity patterns from the mosaic of habitats represented in most allochthonous plant bed (Kędzior and Popa 2013, 2018).

Palynological data tend to be even more problematic for local-scale diversity studies due to variations in how far the palynomorphs have been transported. For instance, pollen of

modern-day *Picea* has been found in the Canadian Arctic, 3000 km from its source (Campbell et al. 1999); in the Palaeozoic, conifer pollen appears to have been blown in from a considerable distance (e.g. Bless et al. 1977); some pollen in Carboniferous tropical palynofloras even appear to have originated from high-latitude, Gondwana vegetation (Dimitrova et al. 2011). Even long-distance water transportation of pollen has been reported; for example, Holocene *Podocarpus* pollen that have been found in Nile delta deposits may have been transported > 2,000 km along the river from their source in the Ethiopian Highlands (Leroy 1992). Although such exotics will normally be rare in palynofloras, they represent the end-members of a gradational spectrum of palynomorph abundances reflecting differences in transportation distances, making it difficult to extract local-scale diversity patterns, especially in fluvial and delta settings (Weng et al. 2006).

Local-scale past plant diversity is best determined in the rare autochthonous fossil floras although even here the data are often incomplete (Section 4.1). Some of the best examples of autochthonous floras preserving forest vegetation including both the trees and herbaceous plants are in Palaeozoic volcanic ash-fall deposits (e.g. Wagner 1989; Rössler and Barthel 1998; Wang et al. 2012; Luthardt et al. 2016). Examples studied in great detail are in an ash band in the early Moscovian Radnice Coal in the Czech Republic, where about 0.5 m of volcanic ash engulfed an area of swamp vegetation. The lower part of the deposit contains in situ stumps and the groundcover vegetation, which, because the ash fell almost vertically, was mostly not winnowed out. The upper parts of the ash band, in contrast, includes remains of the upper parts of the trees, together with epiphytes and lianas, brought down by the weight of the ash sometime after the deposit had fallen (Pšenička and Opluštil 2013). A careful survey of the plant remains in different levels of the ash deposit (Fig. 8) not only allowed the reconstruction of the taxonomic composition, spatial distribution and density of

vegetation cover, but also revealed evidence of plant to plant interactions and living strategies in extraordinary detail (Opluštil et al. 2007, 2009a,b, 2014; Libertín et al. 2009a).

Many coals (but not all – Glasspool 2003) are the remains of parautochthonous peat and so, as with modern-day peat deposits (e.g. Mauquoy et al. 2010), have the potential to reveal local-scale plant diversity. When the peat has changed into coal through compaction and diagenesis, however, the plant remains become homogenised and so difficult to identify. Notable exceptions are when the peat has been subjected to early mineralisation that preserves the anatomy of the plant remains in often exquisite detail. Sometimes most or all the peat deposit has been mineralised (e.g. Galtier 2008; Slater et al. 2015) but more commonly the mineralisation is localised, such as in the coal balls (mainly calcitic nodules) found in some Palaeozoic coal seams. There have been several local-scale diversity studies on coal balls (e.g. DiMichele and Phillips 1988; DiMichele et al. 1991; Willard 1993; Baker and DiMichele 1997; DiMichele et al. 2002; Willard et al. 2007), which produced evidence of biomass allocation within the peat, which in turn gave some localised evidence of species diversity.

Coal deposits often yield well-preserved palynomorphs, which have been extensively used for biostratigraphical studies revealing evidence of the temporal changes in vegetation (e.g. Smith and Butterworth 1967). If intercalated fine-siliciclastic (shaley) coal-bearing samples are also included, palynological assemblages can be particularly species rich. As with the macrofloras, regional to exotic extra-basinal palynomorphs may also be present (Fig. 9), which can be ideal for palynological correlation purposes (e.g. Stolle 2007, 2010), but can confuse local-scale species richness analyses. Palynology has also been used to investigate the ecological development of the swamps (e.g. Smith 1962, 1968; Habib and Groth 1967; Jasper et al. 2010; Johnston et al. 2017; Eble et al. 2019) and to look at plant diversity at the rank of genus and higher (e.g. Dimitrova and Cleal 2007; Libertín et al. 2009b; Thomas and

Dimitrova 2017), but direct translation of the resulting palynological spectra into plant species diversity is difficult.

Another distinctive parautochthonous source of plant remains is amber, mainly of Cretaceous to Neogene age. Amber can be produced by both conifer (Sadowski et al. 2017) and angiosperm trees (Rust et al. 2010), and can result in exquisite preservation, especially of delicate structures such as flowers (Poinar 2002; Gandolfo et al. 2018), fern sori (Sadowski et al. 2019) and even microscopic algae (Schmidt et al. 2006). Some of these deposits have been studied since the middle 19<sup>th</sup> century, but amber can be a very selective fossil trap (e.g. Solórzano Kraemer et al. 2018) and so our understanding of the plant diversity of these forests is still incomplete.

## 5.2 *Landscape-scale diversity*

Studies on compression fossil diversities across depositional basins (e.g. Cleal 2005, 2007, 2008a; Goswami and Singh 2013; Huang et al. 2016; Opluštil et al. 2017; Goswami et al. 2018; Roopnarine et al. 2018; Saxena et al. 2020) tend to be based on plant remains from a narrow band of habitats. For instance, compressions from the Pennsylvanian swamps of Euramerica appear to have been dominated by remains of the vegetation growing on clastic substrates such as flood-plains, levees and sand banks, whereas the peat-substrate vegetation, which in fact dominated these swamps, is often poorly represented (Cleal et al. 2012); the peat-substrate vegetation is, in contrast, better represented in the coal ball floras and palynospectra. This is not a problem if the main aim is to document extrinsic effects such as climate or landscape changes, particularly if the sampled habitats are tightly constrained ecologically, but care must be taken not to over-generalise the results in terms of overall vegetation patterns.

One of the best sources of detailed data on Palaeozoic landscape-scale diversity are the ash deposits in the Czech Radnice Coal (mentioned in Section 5.1), which have been

recorded from numerous localities in both historical collections and several recent excavations. These have allowed lateral variation in the swamp vegetation at one stratigraphical level to be investigated; for instance, studies at the Štílec and Ovčín localities, about 20 km apart, yielded two contrasting assemblages, representing different stages of vegetation succession (Opluštil et al. 2007, 2009a,b, 2014; Libertín et al. 2009a). A similar situation is present in the earliest Permian Wuda ash bed that occurs over an area of more than 60 km<sup>2</sup>, enabling distinct assemblages to be recognised both vertically and laterally (Wang et al. 2012).

Floras with anatomically preserved petrifications and permineralisations are more difficult to use for landscape-scale diversity studies. Most such floras tend to be isolated localities reflecting the exceptional conditions that caused the preservation, and so usually only reflect local-scale diversity. The most notable exceptions are the Pennsylvanian-age coal balls floras that occur extensively across the Late Palaeozoic tropical belt but, although they have been the subject of a number of taxonomic collations (e.g. Phillips 1980; Galtier 1997), no detailed landscape-scale diversity studies have been attempted. In palaeozoological studies, such preservational “hot-spots” have proved a problem by suggesting abnormally high diversities at particular stratigraphical levels, often referred to as the “Lagerstätte effect” (e.g. Benton 1995; Butler et al. 2013), but evidence of this distorting effect on plant fossil diversities is less clear (see comments by Cascales-Miñana and Gerrienne 2017).

Palynology can provide a more representative picture of landscape-scale diversity as the sediment will contain the pollen from plants growing across the area (Weng et al. 2006). This has proved particularly useful in Quaternary studies where the botanical affinities of the various pollen types are well known (Section 4.2). For instance, palynology has been used to map distribution changes across Europe during the Holocene by Huntley and Birks (1983), and there have been numerous species-specific studies (Hicks 2001; Brewer et al. 2002;

Giesecke and Bennett 2004; van der Knaap 2004; Latałowa and van der Knaap 2006; Tinner and Lotter 2006; Giesecke et al. 2007; Pidek et al. 2010; Poska and Pidek 2010). Reitalu et al. (2019) have demonstrated in their study of modern pollen and plant richness across northern Europe that the highest correlations were for trees and shrubs and of wind-pollinated taxa, suggesting that these are the best measures of broad-scale plant richness over several thousands of kilometres.

Improvements in our knowledge of the general affinities of many pre-Neogene palynotaxa (Section 3.2) now allow palynology to identify broad patterns of landscape-scale plant diversity (Abbink et al. 2004; Dimitrova et al. 2005, 2010; Dimitrova and Cleal 2007; Kustatscher et al. 2010; Beri et al. 2018; Franz et al. 2019). However, remaining uncertainties about variations in palynomorph productivity and dispersal between species, and the morphological variation of palynomorphs within plant species, make it difficult to use some taxa for detailed landscape-scale plant diversity studies (Section 4.2).

### 5.3 *Regional-scale and global-scale diversities (Evolutionary floras)*

Studies on global-scale faunal diversity (e.g. Sepkoski 1978, 1979, 1984, 1988; Bambach 1977; Powell and Kowalewski 2002) have shown a progressive increase in species diversity through the Phanerozoic due to an increase in the spatial density of organisms, especially in shallow marine environments (Holland and Sclafani 2015). Similar global and regional studies at the species rank have been attempted in palaeobotany (e.g. Knoll et al. 1979; Niklas et al. 1980) but were hindered by the lack of suitable, taxonomically robust data sets (Section 3.3); also by the failure to take into account geographical (especially latitudinal) variations in taxonomic diversity, as has been shown to be an issue with marine invertebrate diversity dynamics (Close et al. 2020). Analogous palaeobotanical studies would, moreover, be unlikely to answer the same sorts of questions of changes in community structure that were being investigated in the faunal record (Section 4).

Analyses within narrow taxonomic (e.g. Cleal 2008b,c) or stratigraphical (e.g. Cleal et al. 2010; Barbacka et al. 2014) limits have been attempted at the regional-scale, which make it practical for the taxonomic robustness of the data to be critically assessed. However, most larger-scale studies have tended to be based at supra-generic ranks, usually family. For instance, global Phanerozoic plant diversity dynamics were interpreted using Evolutionary Floras (Fig. 10), identified from a factor analysis of a plant family dataset (Cleal and Cascales-Miñana 2014), and these have been used to describe the broad trajectory of vegetation history (Cleal and Thomas 2019; Cleal 2019). More recently, a similar study on pre-Carboniferous floras at the rank of genus is revealing further details of the early phases of plant terrestrialisation (Capel et al., this volume).

There are a number of problems with such large-scale plant diversity studies. The taxonomic robustness of the data used is often uncertain, although for plants this is partly avoided by using family-rank data sets (Section 3.3). More difficult is the robustness of the stratigraphical correlations between widely separated floras. Most fossil floras occur in predominantly terrestrial sequences that lack absolute dating or independent biostratigraphical control (e.g. by marine faunas). In local-scale and landscape-scale studies this is less of a problem as lithostratigraphical correlations are often sufficient to provide a temporal framework for comparisons, but these are inadequate for regional-scale and global-scale studies. The palaeobotanical and palynological evidence is itself sometimes used to provide the correlations, but when this is used as the temporal context for the vegetation changes, the arguments become circular. A classic example is the Panchet Formation in India, which is often quoted as justifying the persistence of glossopterids into the Triassic Period, but for which there is in fact no evidence that it is Triassic other than some debatable facies changes and the floras themselves (Saxena et al. 2018).

## 6 Why study plant diversity in deep time?

Studies of past plant diversity dynamics are particularly important for providing a comparison with models used to describe the response of vegetation to recent climate change (Willis et al. 2010; Reitalu et al. 2014). For instance, the Quaternary record has indicated that glacial-interglacial changes have induced large-scale shifts in plant distributions (Willis and Bhagwat 2009; Giesecke et al. 2017), although there was sometimes a lag between climatic change and vegetation change (Leroy et al. 2011). Some warm-loving and cold-loving deciduous tree species became extinct in Europe during glacial phases (Willis and Niklas 2004; Bertini 2010), due not only to climate change, but also to disease, competition and extreme conditions in refugia (Leroy 2007). For those species that survived the glacial phases, refugia such as in southern Europe were essential (Bennett et al. 1991; Leroy and Arpe 2007). In contrast, conifers and some climatically less sensitive angiosperm trees found refugia further north in Europe during glacial phases (crypto-refugia; Willis et al. 2000; Bhagwat and Willis 2008) whereas herbaceous species typical of tundra and steppe vegetation have been forced into upland refugia during the forest dominated phase of the Holocene (Bennett and Provan 2008). It is evident that these refugia have been vital for the shaping of present-day biogeographical patterns and the assemblage of extant communities (Willis and Bhagwat 2009). Refugia have also been used to explain the responses of vegetation to climate changes in Carboniferous tropical swamps (e.g. Falcon-Lang and DiMichele 2010; Looy et al. 2014).

Palynological research has revealed anthropogenic effects on Holocene plant diversity (Giesecke et al. 2012, 2019). For example, Filipova-Marinova et al. (2014) described an 8,000 year long record of vegetation change at Varna Lake (Bulgaria) and showed how the vegetation was strongly influenced by human activity, both through woodland clearance and the establishment of agriculture.

Rull (2011, 2013) has explored the drivers of neotropical diversity since early Neogene times, and concluded that it is the result of complex ecological and evolutionary trends initiated by tectonic events and palaeogeographical reorganisations, and was maintained by Pleistocene climatic changes. The palynological record during the Palaeocene – Eocene Thermal Maximum indicated an increase in diversity in tropical (Jaramillo et al. 2010) and polar vegetation (Willard et al. 2019), whereas in temperate latitudes the effects were less marked (e.g. Wing et al. 2003) except sometimes for a change to more fire-prone vegetation (Collinson et al. 2009).

Further back in geological time, the analyses are more difficult because we are looking at plants that are only distantly related to modern-day vegetation, but the comparisons can nevertheless be insightful. Many Mesozoic studies have focussed on how vegetation recovered from the Permian – Triassic and Triassic – Jurassic biotic crises (e.g. Grauvogel-Stamm and Ash 2005; Yu et al. 2015). For instance, Hochuli et al. (2016) showed the complex pattern of recovery of the post-extinction, Early Triassic vegetation. Various other floral changes were recorded at the Triassic – Jurassic boundary in Greenland (McElwain et al. 2007) and at the Hettangian-Sinemurian boundary in the South Carpathians (Popa 2000).

In the Palaeozoic, most attention has been directed to the effect of the Late Palaeozoic Ice Age on plant diversity: did the observed Pennsylvanian – Cisuralian diversity changes in the tropical vegetation cause climate change (e.g. Cleal and Thomas 1999, 2005), or did the climate change cause the vegetation changes (e.g. Pfefferkorn et al. 2008, 2017), or were the two interlocked through feedback loops (Cleal et al. 2010)? Other links that have also been explored are between the diversification of the first woody forests in Late Devonian times and a significant change in ocean water chemistry that caused major reduction in marine faunal diversity (Algeo and Scheckler 1998); and between the very early development of

plant diversity during Ordovician times and global cooling and glaciation (Servais et al. 2019).

Another major theme of research has been the effect of mass extinctions on vegetation (McElwain and Punyasena 2007; Cascales-Miñana et al. 2013). Clearly extensive destruction of vegetation occurred during three of the five classic “mass extinctions” of Sepkoski (1978, 1979, 1984): at the boundaries between the Permian – Triassic (e.g. Looy et al. 1999; Hochuli et al. 2016, 2017), Triassic – Jurassic (e.g. McElwain et al 2007; Mander et al. 2013; McElwain 2018) and Cretaceous – Palaeogene (e.g. Vajda and Bercovici 2014). However, a key criterion for recognising a true mass extinction (Raup and Sepkoski 1982) is that it should significantly disrupt the overall trajectory of evolution and this did not occur with plants at most of these biotic crises (McElwain and Punyasena 2007; Cascales-Miñana 2011, 2012; Cascales-Miñana and Cleal 2011; Cascales-Miñana and Diez 2012; Cascales-Miñana et al. 2013). Only at the Permian – Triassic boundary does there seem to have been any significant clade disruption (Cascales-Miñana and Cleal 2014; Cascales-Miñana et al. 2016), and even here the pattern of extinction was more complex than with the marine faunas (Hochuli et al. 2016; Nowak et al. 2019). The fossil record seems to suggest that plants were much less vulnerable to biotic crises compared with faunas (Traverse 1988; McElwain and Punyasena 2007; McElwain et al. 2007; Cascales-Miñana et al. 2018).

Identifying vegetation diversity patterns at all scales from the plant fossil record is clearly not easy; whatever the sampling protocol and analytical methods used, the fact will remain that the observed diversity patterns are of the fossils rather than purely of the original vegetation. Nevertheless, the fossil record is the only direct evidence we have of how vegetation has changed through time. By bringing together data from the palaeobotanical and palynological records and interpreting it within the context of the taphonomic filter through which the fossils have passed (Fig. 11) will allow us to understand better how plant-life has

responded to changes in climate, landscape and continental configurations, and to the dramatic ecological crises often referred to as mass extinctions.

## 7 Conclusions

A deeper appreciation of the history of vegetation dynamics can inform present-day landscape management and predictions of future biodiversity and climate. For example, the plant fossil record can provide evidence of the speed at which plants can track climate change and this may prove valuable to predict the response of today's plant vegetation to global warming. It can also provide empirical data to help support and improve models of the dynamic interactions of modern-day vegetation, atmosphere and climate. Evidence from the fossil record clearly has the potential for making a significant contribution to understanding the world today, and emphasises the importance of close co-operation between palaeoecologists and ecologists. Provided that the context of the data is properly understood, including the taxonomy of the fossils (not just the taxonomic names used but what the fossil-taxa mean), the taphonomic processes that caused the fossil to be preserved, and the detailed temporal (stratigraphical) correlations, an underlying signal of vegetation diversity remains waiting to be discovered.

## Acknowledgements

The authors are grateful to the European Science Foundation for supporting the Exploratory Workshop entitled *Tracking changes in plant diversity over the last 400 million years*, held in 2014 at National Museum Wales, Cardiff, UK. Ian Glasspool is thanked for providing the images used in Fig. 3. This is a contribution to National Museum Wales Research Project NS25 *Plant diversity through 450 million years of Earth history*.

1689 Figure captions

1690 Fig. 1. Variation in productivity of different organs of a plant as illustrated by the pollen,  
1691 flowers, leaves, shoots, stem and roots of a hypothetical modern-day angiosperm tree.

1692 Redrawn and adapted from Hughes (1976, fig. 3.6) and Cleal and Thomas (2019, fig. 10.4).

1693 Fig. 2. Three types of diversity that can be recognised in the plant fossil record, using the  
1694 Middle Pennsylvanian (c. 310 Ma) swamp vegetation of Variscan Euramerica, based on Cleal  
1695 et al. (2012).

1696 Fig. 3. Morphological similarity of late Permian gigantopterid leaves (A, C, *Gigantonoclea*  
1697 *hallei* (Halle) Wang) and modern angiosperm leaves (B, *Castanea sativa* Miller; D, *Quercus*  
1698 *robur* L.). All scale bars = 10 mm. A, C, Naturhistoriska Riksmuseet (NRM), Stockholm (A,  
1699 NRM S128498; C, NRM S128494), B, D, Royal Botanic Gardens Edinburgh herbarium  
1700 (RBGE). Adapted from Glasspool et al. (2004).

1701 Fig. 4. Partial reconstruction of the Late Devonian seed plant *Elkinsia* based on associated  
1702 fronds, ovulate structures and anatomically preserved stems. Drawn from by Annette  
1703 Townsend (based on Serbet and Rothwell 1992).

1704 Fig. 5. Examples of the differences in the fossil-genera represented by Carboniferous  
1705 arborescent lycopsids and sphenopsids. Adapted from Cleal and Thomas (2019).

1706 Fig. 6. Spores of fern *Weischelia reticulata* (Stokes and Webb) Fontaine showing different  
1707 maturation stages; Escucha Formation (Albian), Escucha, northern Teruel Province, Spain. A,  
1708 General view of a soral cluster up to 2 mm in diameter showing tightly packed peltate  
1709 indusia. B, Tightly-packed spores grouped inside a receptaculum. C, Inaperturate, discoidal  
1710 spores with smooth exine and lacking trilete mark. D, Packed spores showing different  
1711 ontogenetic stages. D, E, Fully-developed tetragonal spores with well-rounded corners and

1712 clear trilete scar. Original unpublished material from the study in Diez et al (2005) with  
 1713 permission of the authors.

1714 Fig. 7. T<sup>0</sup> fossil or submerged forests of arborescent lycopsids in the Carboniferous of the  
 1715 UK. A, Fossil trees rooted in a coal seam being exposed at Brymbo, north Wales (Appleton et  
 1716 al. 2010). B, Excavated trees in the Victoria Park, Glasgow (Thomas and Seyfullah 2015).

1717 Fig. 8. Palaeozoic wetland vegetation preserved in the lower unit of the early Moscovian  
 1718 Whetstone Horizon (Bělka tuff), Ovčín, Central Bohemia, Czech Republic. A, Remains of  
 1719 cordaites and arborescent lycopsids plotted out on an exposed area of the tuff divided into 1  
 1720 m<sup>2</sup> quadrats; the small number against each specimen represents the height above the base of  
 1721 the tuff that the fossil occurred. B, Reconstruction of forest based on the type of plots shown  
 1722 in Fig. 7A. From Opluštil et al. (2014).

1723 Fig. 9. Comparison of palynological and macrofloral spectra obtained from roof-shales  
 1724 overlying four Moscovian-age coal seams in South Wales, UK, between the Daren Ddu Seam  
 1725 at the base and the Llantwit No. 1 Seam at the top. Redrawn from Dimitrova et al. (2005, fig.  
 1726 4).

1727 Fig. 10. Range of basinal and extra-basinal vegetation represented in Moscovian (late  
 1728 Carboniferous) palynospectra from the Sydney Coalfield, Cape Breton, Canada (Dimitrova et  
 1729 al. 2011).

1730 Fig. 11. The Evolutionary Floras model of vegetation evolution based on a factor analysis of  
 1731 global plant-family distribution through the Phanerozoic (Cleal and Cascales-Miñana 2014).

1732 Fig. 12. Factors that affect how we interpret past vegetation diversity from the macrofloral  
 1733 and palynological records, demonstrating the importance of integrating the two sets of data.

Table 1. Fossil-genera assigned to different parts of six representative plants from the main groups in the late Carboniferous tropical coal swamps. The fossil-genera selected to represent each plant group in taxonomic diversity studies (e.g. Cleal et al. 2012) designated by an asterisk (\*). This does not include the pollen/spores produced by these plants.

		Lycospids	Calamites	Sphenophylls	Marattialean	Medullosaleans	Cordaite
Stems		<i>Lepidophloios*</i>	<i>Calamites</i>	<i>Sphenophyllum*</i>	<i>Caulopteris</i>	-	<i>Artisia</i>
Foliage		<i>Cyperites</i>	<i>Annularia*</i>			<i>Alethopteris*</i>	<i>Cordaite*</i>
Reproductive structures	Female	<i>Lepidocarpon</i>			<i>Cyathocarpus*</i>		
		<i>Lepidostrobophyllum</i>	<i>Calamostachys</i>	<i>Bowmanites</i>		<i>Trigonocarpus</i>	<i>Cardiocarpus</i>
	Male	<i>Lepidostrobus</i>				<i>Whittleseya</i>	<i>Cordaitanthus</i>
Rooting structures		<i>Stigmara</i>	<i>Pinnularia</i>	-	-	-	-
Total fossil-genera		6	4	2	2	3	4
