43 Long-term changes in radiative forcings (CO_2 , orbital variations) are thought to be the primary driver of
44 the Cenozoic evolution of the Antarctic Ice Sheets (AIS), but the tectonic evolution of Antarctica may
45 also have played a substantive role. Deep-sea foraminiferal oxygen isotope records ($\delta^{18}\text{O}$) provide a
46 combined measure of global continental ice volume and ocean temperature, but do not provide direct
47 insights on non-radiative influences on AIS dynamics. Here, we generate the first Antarctic-proximal
48 (Ross Sea and Wilkes Land) Cenozoic compilation of upper ocean temperature, and find that trends of
49 ocean temperature, atmospheric CO_2 and $\delta^{18}\text{O}$ do largely co-vary. However, this relationship is less
50 clear for the late Oligocene, when high latitude cooling occurred, despite $\delta^{18}\text{O}$ values implying global
51 warming and ice volume loss. We propose West Antarctic Ice Sheet retreat occurred in response to a
52 tectonically-driven marine transgression at this time, with warm surface waters precluding marine-based
53 ice sheet growth. Marine-based ice sheet expansion only occurred when ocean temperatures cooled
54 enough during cold orbits and low atmospheric CO_2 at the Oligocene-Miocene transition. Our results
55 support hypotheses of a threshold response to atmospheric CO_2 , below which Antarctica's marine ice
56 sheets grow, and above which ocean warming exacerbates their retreat.

57

58 It is well-known that the AIS is sensitive to multi-millennial scale variations in Earth's astronomical
59 configuration¹⁻⁴. However, million-year timescale trends in AIS volume are generally controlled by
60 more gradual changes in greenhouse gas concentrations⁵, changing continental configurations
61 modulating heat flow towards Antarctica⁶, and topographic changes driven by subsidence and erosion
62 on the continent^{7,8}. Benthic deep sea $\delta^{18}\text{O}$ records provide critical insights into Cenozoic climate
63 variability^{3,9}, but are a signal of both deep ocean temperature and global ice volume change, and

64 additional information from Antarctic-proximal archives are required to fully understand the controls
65 on past AIS dynamics.

66

67 Models and near-field geological data indicate the AIS in the Ross Sea region is sensitive to climate
68 forcings such as local insolation, ocean heat flux and local sea level changes, and records variability of
69 both the East (EAIS) and West Antarctic Ice Sheets (WAIS)^{1,10–12}. Millions of years of erosion,
70 sedimentation, thermal subsidence and tectonic rifting in the Ross Sea^{7,8} have resulted in West
71 Antarctica evolving from an elevated and subaerial region capable of sustaining a large terrestrial ice
72 sheet in the Oligocene¹³, to the present day over-deepened, subsided continental shelf bathymetry
73 occupied by marine-based ice sheets (Fig. 2a)^{7,14,15}.

74

75 Here, we investigate the role of climatic and non-climatic drivers on long-term AIS variability by
76 examining the relationship between high-latitude temperature, atmospheric CO₂ and ice volume. We
77 hypothesize that if AIS volume changes were driven directly by radiative forcing and related ocean
78 temperatures, then Southern Ocean sea surface temperatures (SST) should largely covary with
79 atmospheric CO₂ and benthic $\delta^{18}\text{O}$ records. To test this, we reconstruct Cenozoic upper ocean
80 temperatures in the Ross Sea and Wilkes Land margin region from a compilation of sediment and
81 outcrop samples (Fig. 1) using glycerol dialkyl glycerol tetraethers (GDGTs), membrane lipids formed
82 by archaea and some bacteria¹⁶ (Supplementary Information S1). We apply the recently developed
83 OPTiMAL machine learning-based temperature calibration to new and legacy GDGT datasets to assign
84 SST estimates (average standard deviation is 3.61°C)¹⁷. We compare these to other GDGT-based

85 temperature calibrations and temperature estimates from fossil assemblages and other geochemical
86 datasets at high southern latitudes (Supplementary Information S1 and Supplementary Table S1).
87 Compiling a long-term Cenozoic Antarctic proximal temperature record necessitates the use of multiple
88 core sites across a complex glacimarine continental shelf to rise depositional transect, influenced by
89 changing water masses and the proximity of ocean fronts. This is particularly the case for Integrated
90 Ocean Drilling Program (IODP) Site U1356 on the Wilkes Land continental rise. This site is proximal
91 to the southern boundary the Antarctic Circumpolar Current (ACC) where glacial-interglacial (G-I)
92 scale variability is influenced by frontal migration^{18,19} (Fig. 1), compared to sites located >14° of
93 latitude further south in the Ross Sea (Fig. 1). These caveats are discussed in more detail in
94 Supplementary Information S2.

95

96 **Cenozoic SST compilation**

97 Mid-Eocene (~48-38 Ma) Ross Sea glacial erratics, eroded from subglacial strata and deposited during
98 subsequent ice sheet advances (Fig. 1; Methods; paleolatitude of ~80°S) display highly variable
99 OPTiMAL SSTs (average ~10 °C; maximum values reaching 20 °C), likely reflecting a range of
100 climate states and/or depositional environments over a wide time range (Fig. 2d)²⁰. Such values are
101 consistent with temperate terrestrial palynomorph assemblages, shark teeth, mollusc assemblages and a
102 probable crocodile tooth (Supplementary Table 1). Mid and upper Eocene SSTs in the CIROS-1 drill
103 core (Fig. 1, Extended Data Fig. 1) indicate Ross Sea temperatures were 4-6.5 °C by ~36 Ma (Fig. 2),
104 consistent with a range of qualitative indicators of Southern Ocean cooling and ice growth ~2 million
105 years prior to widespread AIS expansion across the Eocene Oligocene Transition (EOT; 34 Ma)

106 (Supplementary Table 1)^{21,22}. During the EOT (Fig. 2), Ross Sea SSTs dropped to as low as 2.4 °C,
107 comparative with mid- to high-latitude Southern Ocean cooling of ~5 °C²³. By the early Oligocene,
108 SSTs warmed again, reaching similar values to the late Eocene (~4-6 °C) (Fig. 2), a warming also
109 observed at the Wilkes Land margin (Site U1356; Fig. 1). However, at this more northern site
110 (paleolatitude of ~59°S) SSTs were significantly warmer (reaching 15-20 °C), with a ~10-15 °C
111 temperature gradient reflecting the ~14 degrees latitudinal offset (~1650 km) between sites in our
112 compilation, as well as warmer lower-latitude water masses bathing the Wilkes Land margin prior to
113 Tasmanian Gateway widening¹⁸.

114
115 A substantial latitudinal temperature gradient persisted throughout the Oligocene, although both regions
116 experienced cooling at ~25 Ma (Fig. 2 and 3). Following the Oligocene-Miocene Transition (OMT; ~23
117 Ma), Ross Sea SSTs in the early Miocene averaged 3 °C (standard deviation of 1.5°C), with variability
118 likely driven by astronomically-paced climate cycles. GDGT-based SSTs in the Ross Sea during the
119 Miocene Climate Optimum (MCO; ~17-15 Ma) average 2.2 °C (standard deviation of 1.5°C). However,
120 warmer values up to 6-8 °C occur during peak MCO warmth (Fig. 2)¹¹, comparable with estimates from
121 carbonate clumped isotope (Δ_{47}) analysis and leaf wax isotopes in AND-2A cores (Fig. 1)^{11,24}, and
122 vegetation assemblages in Transantarctic Mountain lake sediments²⁵ (Supplementary Table S1). Wilkes
123 Land SSTs remained warmer than the Ross Sea, averaging 7.5 °C, with a larger standard deviation of
124 3.6 °C (Fig. 2) attributed to warm-water incursions due to weakened Southern Ocean frontal systems
125 that influence Site U1356¹⁹. The middle Miocene Climate Transition (MMCT, ~14.6-13.8 Ma) is
126 characterised by Ross Sea SSTs averaging ~2.5 °C, but not exceeding 5 °C, although only five samples

were examined due to extensive erosion from continental shelf-wide ice-sheet grounding events limiting availability of datable stratigraphic material^{11,15}. Across the MMCT, surface cooling and decreasing temperature gradients between Wilkes Land and the Ross Sea likely reflects intensification or southward migration of the Antarctic Divergence proximal to Site U1356 (Fig. 2). Early Pliocene Ross Sea GDGT-based SSTs derived from AND-1B (Fig. 1) averaged ~6°C, consistent with diatom assemblages and evidence of limited summer sea ice during peak interglacials of the early Pliocene²⁶. Such surface temperatures are consistent with mid-Pliocene global mean annual SST reconstructions of 2-3 °C above pre-industrial, assuming 2-3x polar amplification²⁷. The return to warm values similar to the Oligocene and MCO seems surprising at face value, but AND-1B is inherently biased toward interglacial values (Supplementary Information S2). In addition, the warmest temperatures in AND-1B occur during the transitions into and out of the peak interglacial intervals, when sedimentary facies and geochemical proxies indicate enhanced glacial meltwater processes and seasonal sea ice melt, which acts to enhance thermal stratification and warm upper ocean temperatures²⁶. Cold temperatures of 1-3°C predominantly characterised the late Pliocene-Pleistocene in the Ross Sea (Fig. 2).

Late Oligocene ice sheet retreat in a cooling climate

Our 46 million-year Ross Sea temperature record shows a trend of ocean cooling in concert with declining atmospheric CO₂ and increasing benthic foraminiferal $\delta^{18}\text{O}$ values^{3,28,29}, implying high latitude temperature and ice volume are largely coupled over the Cenozoic (Fig. 2). However, this relationship is notably weaker during the late Oligocene (Fig. 3). Following a positive isotope excursion at ~27 Ma (Oi2b event), average $\delta^{18}\text{O}$ values then decrease by -0.4 to -0.6 ‰ over a ~3 million year

148 period, a trend widely interpreted as an interval of prolonged global warming⁹. Evidence of circum-
149 Antarctic warm conditions between 27 and 25 Ma include (i) warm-water nannofossil assemblages over
150 Maud Rise and the Kerguelen Plateau³⁰, (ii) Ross Sea dinocyst assemblages and TEX₈₆-based SSTs
151 (DSDP Site 274)³¹, and (iii) dinocyst and sedimentary evidence of limited sea ice and ice-rafted debris
152 from offshore Wilkes Land^{32,33}. In the Ross Sea, late Oligocene surface water temperature data are
153 lacking prior to 25.5 Ma in DSDP Site 270, with samples between 25.5-25 Ma recording relatively
154 warm SSTs (~6-7°C) and diverse foraminifera assemblages with more temperate affinities compared to
155 younger Oligocene assemblages³⁴.

156
157 After ~25 Ma, the deep sea $\delta^{18}\text{O}$ record continues to trend towards lower values, implying warming
158 (Fig. 3), yet our temperature reconstructions show ocean surface cooling in the Ross Sea and Wilkes
159 Land. Paleoenvironmental proxies also suggest SST cooling and sea ice cover at this time in the Ross
160 Sea, including nannofossil, marine palynomorph, and marine macrofossil assemblages in uppermost
161 Oligocene sediments from Cape Roberts Project (CRP)³⁵ (Supplementary Table 1). Sedimentary facies
162 analysis, and chemical weathering indicators in the CRP and CIROS-1 cores also suggest a minimal
163 change or a long-term cooling trend during the late Oligocene, with conditions periodically cold enough
164 to allow for orbitally-paced marine-based EAIS outlet glacier advance into the western Ross Sea
165 (Supplementary Table 1)⁴. Seismic disconformities also indicate Wilkes Land continental shelf marine-
166 based ice advance also occurred after ~25 Ma, and are associated with mass transport deposits on the
167 continental rise at IODP Site U1356³³ (Supplementary Table 1).

168

169 The contrast of a cooling Antarctic climate from ~25 Ma with inferred warming and/or ice volume
170 decrease from deep sea $\delta^{18}\text{O}$ records has previously been attributed to reduced proto Antarctic Bottom
171 Water formation, and increased warmer, Northern Hemisphere-sourced deep waters influencing drill
172 sites north of the ACC^{36,37}. While this may explain the latitudinal $\delta^{18}\text{O}$ gradient, it does not fully explain
173 the trend to lower $\delta^{18}\text{O}$ values (reaching a minima at ~24 Ma) in both the Pacific and Atlantic oceans
174 (Fig. 3), especially if the precursor surface waters that form Antarctic Bottom Water in the Ross Sea are
175 cooling as our SST compilation implies. There is also considerable heterogeneity in global SST records
176 over this time³⁸, with high southern latitudes (discussed here) and equatorial Atlantic records suggesting
177 warming peaked between 26 and 25 Ma, while North and Southwestern Atlantic records show
178 continued warming until 24-23.5Ma³⁸. In the context of these records, we present a hypothesis that
179 reconciles evidence of Antarctic cooling on a background of subsidence-driven ice sheet retreat in West
180 Antarctica, that we argue provides a mechanism to explain the observed trends in global ocean $\delta^{18}\text{O}$ and
181 globally distributed ocean temperature records for the Late Oligocene^{37,38}.

182
183 Ice sheet modelling studies that use restored Antarctic paleotopographies show a largely subaerial West
184 Antarctica in the Oligocene could accommodate a much larger reservoir of terrestrial ice than today,
185 even with warmer-than-present ocean temperatures in the Ross Sea^{7,8,39,40}. Marine-based ice is
186 inherently more sensitive to ocean warming, and retreat is exacerbated by non-linear processes³⁹⁻⁴¹. We
187 suggest that a transgression of relatively warm water across West Antarctica due to tectonic subsidence
188 and glacial erosion drove ocean-induced retreat of the terrestrial WAIS, resulting in a gradual and
189 progressive decrease in ice extent and volume in warmer-than-present late Oligocene climates. The

evidence for regional tectonic subsidence comes from a dense network of seismic reflector correlations to DSDP Site 270, for which age control and paleodepth reconstructions show an extended episode of late Oligocene deepening of the sea-floor between ~26 Ma and the early Miocene^{7,15,34,42} (Fig. 3). Terrestrial to shallow marine sediments at the base of DSDP site 270 are overlain by mudstones with benthic foraminiferal assemblages indicating water depths of ~200 m between 25.5-24.8 Ma, deepening to ~500 m by ~24.5 Ma, with ongoing subsidence continuing after this time (Fig. 3). As the mid-Ross Sea paleocontinental shelf subsided below sea level, and despite cooling of local SSTs, ocean temperatures remained too warm (Fig. 3) for significant marine-based ice development, driving a long-term decrease in Antarctic ice volume and contributing to the decreasing trend in global benthic $\delta^{18}\text{O}$.

Model experiments show that under constant atmospheric CO_2 concentrations of 500 ppm, changes in bed elevation alone between EOT and OMT topographies can account for an ice volume difference of $5.7 \times 10^6 \text{ km}^3$ using the ‘median’ reconstruction of ref. ⁸ (see Methods). Interestingly, a larger, terrestrial WAIS serves to buttress and increase the size of the EAIS, and subsidence-driven retreat in the Ross Sea would also lead to a significant loss of the inland EAIS⁴³. If most of the subsidence between the EOT and OMT occurred in the late Oligocene, as indicated by seismic data and the DSDP site 270 reconstructions, then subsidence could account for ice loss equating to an average $\delta^{18}\text{O}$ shift of -0.2 ‰ (see methods)³⁹. However, this example was performed under constant climate state, feedbacks in the earth system or orbitally driven climate changes over long-time periods are not accounted for in this estimate. The total $\delta^{18}\text{O}$ decrease from Oi2b at 26.7 Ma to 24 Ma is on the order of -0.4 to -0.6 ‰, and it is likely that the earliest phase of this signal was indeed amplified by climate-driven retreat following

211 the warming out of the ~27 Ma Oi2b glacial event¹⁸. However, following the initiation of cooling in our
212 compilation at ~25 Ma, $\delta^{18}\text{O}$ declines by a further ~0.05-0.2 ‰ (Fig. 3a), which is consistent with
213 continued long term tectonic-driven retreat. As noted earlier, this signal has previously been explained
214 by heterogeneity in deep water temperature signals^{36,37} and indeed tectonically-driven Late Oligocene
215 marine AIS retreat could have driven this heterogeneity. Models for the Pliocene show AIS loss in West
216 Antarctica and Wilkes Land acts to slow the ACC and Pacific Ocean overturning circulation - leading to
217 reduced AABW formation, increased heat transport to the North Atlantic, and divergence of global deep
218 water mass temperatures in the Pacific and Atlantic ocean⁴⁴. Shifts in ACC circulation and zonal winds
219 relating to contracted AIS volume could also shift surface water connectivity between the ocean basins,
220 and wind-driven upwelling systems²⁶, contributing to the significant heterogeneity in global surface
221 water trends through this time³⁸.

222
223 In summary, we suggest that a continuous decline in average ice sheet volume occurred between ~27-24
224 Ma. This was likely driven initially by the shift to warmer climatic conditions following the 27 Ma Oi2b
225 glacial event¹⁸, but despite subsequent cooling from ~25 Ma in the Ross Sea and Wilkes Land, the
226 marine sectors of AIS continued to retreat due to basin subsidence and marine incursion across West
227 Antarctica (Fig. 3). Ross Sea SSTs had cooled to ~3 °C by 24.5 Ma, coinciding with a 1.2 Myr node in
228 obliquity, an astronomical configuration favourable to ice sheet expansion². Proximal glacimarine
229 sedimentary facies were deposited at DSDP site 270 at this time and mark a period of ice sheet
230 grounding line advance into the Ross Sea (Fig. 3)^{42,45}. A major increase in obliquity sensitivity (S_{obl}) is
231 also observed at ~24.5 Ma, a metric associated with marine ice sheet advance and enhanced AIS and

ocean connectivity (Fig. 3)⁴⁵. Atmospheric CO₂ records through the Oligocene are sparse and there is still considerable uncertainty surrounding the absolute values assigned to individual data points, but a clear decline in CO₂ values occurs between the early and late Oligocene (Fig. 2)^{5,46}. Pleistocene to Pliocene-based model-data comparisons^{1,8,41} suggest values much lower than 400 ppm (e.g. ~280 ppm) are required for marine ice sheet advance onto the mid-continental shelf of the Ross Sea, while above 400 ppm marine-based ice is absent from West Antarctica, and sectors of East Antarctica⁴¹. Higher-resolution atmospheric proxy CO₂ records, alongside further validation of absolute values, in this critical interval would allow for a better understanding of these thresholds. However, the episode of marine ice sheet advance at 24.5 Ma was transient, and relatively muted in scale in the $\delta^{18}\text{O}$ record. Following this, a trend towards a smaller WAIS is reflected by deeper water, ice distal facies in the latest Oligocene in DSDP site 270 (Fig. 3)^{34,42} and the continued decrease in average deep sea $\delta^{18}\text{O}$ until 24 Ma.

After 24 Ma, Ross Sea SSTs continued to cool, crossing a threshold to enable marine-based ice sheets to migrate across the deep continental shelf (Fig. 3). This culminated in the Mi-1 glaciation at 23 Ma, which peaked during a 400 kyr eccentricity minimum and a 1.2 Myr node in obliquity, an optimal configuration for ice growth due to extended low seasonality and cool summer temperatures². Some proxy atmospheric CO₂ reconstructions suggests values reached as low as 265 ppm ($2\sigma_{-111}^{+166}$ ppm) during Mi-1⁴⁷. The Mi-1 event is associated with regional seismic unconformities¹⁵, and major disconformities in DSDP site 270⁴² and CRP-2/2A⁴, while $\delta^{18}\text{O}$ records indicate it lasted ~200-300 kyrs before rebounding in the earliest Miocene towards late Oligocene values. This is consistent with a rapid

253 increase in atmospheric CO₂⁴⁷, an astronomical configuration favouring warming, and marine-based ice
254 sheet retreat over the subsided Ross Sea continental shelf. Between 17.8-17.4 Ma, SSTs of ~1.5-3.4°C
255 at AND-2A indicate the threshold for marine-based WAIS advance was again crossed, as evidenced by
256 recent provenance studies from IODP Site U1521 indicating a large WAIS advance resulted in further
257 lowering of elevations in the interior of West Antarctic via glacial erosion⁴³.

258

259 Our compilation of proximal Antarctic temperatures provide climatic constraints on the late Oligocene
260 expansion of marine-based ice sheets, on the background of competing influences on AIS volume
261 resulting from crustal subsidence in West Antarctica. These results are consistent with the concept of a
262 threshold response suggested by previous studies to occur at atmospheric CO₂ values of ~400
263 ppm^{1,10,11,45}, above which ocean warming at Antarctica's margin greatly exacerbates marine ice sheet
264 retreat into interior subglacial basins, with profound consequences for global sea level.

Methods

Sampling Sites and Age Models

Proximal Antarctic cores contain frequent unconformities, which is often the product of ice sheet overriding or other erosional processes in a glacialmarine environment. In order to compile a long-term Cenozoic record of ocean temperatures from the Ross Sea, this has necessitated using multiple sampling sites and core sites from across the region (Fig. 1). We present data from the McMurdo Erratics, CIROS-1, DSDP 270, CRP-2A and DSDP 274, and compile this with previously published data from ANDRILL 1B and 2A. Age models have been developed using published age datums (Supplementary Data Table 3), but in order to ensure a consistent approach for assigning ages to core depths between datums, we use the Bayesian age-depth modelling functionality in the R package Bchron (Supplementary Data Table 3)⁵¹. The sites included in the Ross Sea compilation are detailed below. We

311 have compared our Ross Sea compilation to a previously published dataset from IODP U1356, offshore
312 the Wilkes Land margin, with GDGT abundances, age model and lithologies^{18,33,52}.

313 **McMurdo Erratics**

314 The oldest sediments used in this compilation are glacial erratics, collected from the Mount Discovery
315 and Minna Bluff region (Fig. 1)⁵³. The erratics have been eroded from sediments deposited in sub-ice
316 basins in the western Ross Sea associated with early Cenozoic rifting during Gondwanaland breakup.
317 These rift-fill sediments were subsequently eroded (likely from the Discovery Deep region) and
318 transported to surficial morainal deposits by expanded ice sheets during past glacial periods. The
319 erratics sampled in this study were deposited in coastal-terrestrial and nearshore marine environments⁵³.
320 Ages for the erratics from the volumes in Harwood and Levy (2000)⁵³ have been updated to most recent
321 ages for the described taxa (Supplementary Data Table 2).

322 **CIROS-1**

323 The CIROS-1 core was drilled in McMurdo Sound in 1986 (Fig. 1)⁵⁴. The upper part of the core (366-0
324 mbsf) is glacially influenced, with major glacial advances represented by massive and stratified
325 diamictites⁵⁵. Below an unconformity, the lower sequence of the core (702-366 mbsf) displays
326 significantly less subglacial influence, containing marine mudstones and sandstones, but with ice rafted
327 debris indicating the presence of marine terminating glaciers at the coastline⁵⁵. The upper part of the
328 core is late Oligocene/early Miocene in age⁵⁶. Age control for the lower part of the CIROS-1 core has
329 undergone a series of revisions since recovery in 1986⁵⁷⁻⁵⁹. Our age model for the Eocene-Oligocene

boundary interval is an improvement on previous attempts, as we incorporate new observations of dinoflagellate cysts with occurrences recently described in other Antarctic and Southern Ocean cores^{52,60–62}. These new observations allow precise constraint of the updated paleomagnetic record⁵⁹ of to the geomagnetic polarity timescale⁶³. In addition, we include updated range data to constrain the ages of biostratigraphic events previously identified in the core. Microfossil reworking has long been recognised as a significant problem in the glacial sediments of Antarctica^{64–66}. In constructing our age model, we have given preference to ensuring conformity to biostratigraphic first occurrences, and are much less concerned about apparent last occurrences in this setting. In addition to the biochronologic controls, we include new $^{87}\text{Sr}/^{86}\text{Sr}$ isotope ratio ages from disarticulated bivalves between 460 and 470 mbsf in the core. Measurements were undertaken at the CSIRO laboratory in Sydney. These ages are interpreted to represent minimum ages.

Biostratigraphic datums are shown in Supplementary Data Table 1, the age-depth chart in Extended Data Fig. 1, and tie points of Age Model 1 used for linear extrapolation of environmental proxies in Supplementary Data Table 3. Four age models were explored; Model One is preferred. Model One and Model Two minimise inconsistency with biostratigraphic first occurrences, place the E-O boundary at 547 mbsf, and assign the interval of normal polarity between 435 and 503 mbsf to Chron C13n. Model One and Model Two place different priority on inconsistencies with biostratigraphic last occurrences, and the robustness of intervals of magnetic reversals constrained by only a few observations. Model One minimises inconsistencies with the geomagnetic polarity record, but does not seek to minimise biostratigraphic last occurrences. In contrast, Model Two requires that the intervals of normal polarity at

351 408 m and 421 mbsf, constrained by only one and two measurements of magnetic polarity
352 respectively⁵⁹, are a transient, local signal not reflective of the global magnetic field. Models Three and
353 Four explore the possibility that the interval of normal polarity between 435 and 503 mbsf is Chron
354 C15n (Model Three) or Chron C12n (Model Four). Model Three is the most unlikely, as it contains
355 seven inconsistencies with biostratigraphic first occurrences across four fossil groups. Model Four is
356 consistent with the paleomagnetic record, and the biostratigraphic first occurrences, but is inconsistent
357 with every available biostratigraphic last occurrence. It would also require a pronounced increase in the
358 proportion of protoperidinioid dinoflagellates cysts observed between 495 and 530 mbsf to have
359 occurred more than 2 million years later than observed in other circum-Antarctic cores⁶².

360

361 One perplexing aspect of the CIROS-1 biostratigraphy is the virtual absence of the dinoflagellate cyst
362 *Malvinia escutiana*, which has a first occurrence in the earliest Oligocene in other Southern Ocean
363 records⁶¹. A single specimen of *M. escutiana* was recorded in CIROS-1, at 376.39 mbsf, within
364 Subchron C11n.2n of age Model One (this study). *M. escutiana* has been identified in the nearby CRP-
365 3 core⁶². Those authors do not report their count data for their CRP-3 dinoflagellates cysts, but note that
366 specimens of *M. escutiana* were recorded somewhere in the interval between 13.4 and 151.97 mbsf.
367 Following the age model for CRP-3 (Age Model 3⁶⁷), this would place the CRP-3 occurrences of *M.*
368 *escutiana* within Chron C12n to upper C12r. This suggests *M. escutiana* may not have a significant
369 presence in the Ross Sea in the earliest Oligocene, in contrast to observations on the Wilkes Land
370 margin at IODP Site U1356^{52,62}.

371 **DSDP 270**

372 Deep Sea Drilling Project Site 270 was recovered from the Eastern Basin of the central Ross Sea in
373 1973 (Fig. 1)⁶⁸ (The Shipboard Scientific Party, 1975a). This core records a deepening sequence of
374 glacimarine sediments, represented by glacimarine mudstones, interstratified mudstones and sandstones,
375 and massive and stratified diamictites^{34,42,68}. Samples for this study have been taken from glacimarine
376 sediments between 387.9 and 27.8 mbsf, dated as late Oligocene to early Miocene⁴².

377 **CRP 2/2A**

378 The Cape Roberts Project recovered CRP 2/2A off the Victoria Land coast of Antarctica in 1999 (Fig.
379 1)³⁵. Samples have been taken from three glacimarine sediment sequences in the upper Oligocene/lower
380 Miocene section of the core, recording the expansion and contraction of the East Antarctic Ice Sheet
381 (EAIS)^{69,70}.

382 **ANDRILL-2A**

383 The AND-2A core was recovered in 2007 from Southern McMurdo Sound as part of the ANDRILL
384 program (Fig. 1)¹¹. Samples for this compilation were collected from the lower Miocene to mid-
385 Miocene section of the core, and were published as $\text{TEX}_{86}^{\text{L}}$ values¹¹, calibrated to Kim et al. (2012)⁷¹
386 (Supplementary Data Table 4). Glacimarine sediments through this section represent ice-distal to ice-
387 proximal, and occasionally subglacial settings, reflecting advance and retreat of grounded ice across the
388 drill site^{72,73}.

389 **DSDP 274**

390 DSDP Site 274 was drilled on the lower continental rise in the northwestern Ross Sea in 1973 (Fig. 1)⁶⁸.
391 Samples for this study were taken from middle Miocene diatom-rich silty clay at 156-142 mbsf. Ages
392 have been assigned using the relaxed hybrid CONOP model of Crampton et al. (2016)⁷⁴ (Supplementary
393 Data Table 3). This model does not extend below 141.26 mbsf. For samples below this depth, the same
394 linear sedimentation rate that occurs above 141.26 mbsf is used. This is constrained by the first
395 appearance of *Denticulopsis maccollumii* at 141.26 mbsf (dated to 17.05 Ma) and the first appearance of
396 *Actinocyclus ingens* at 113.6 mbsf (dated to 15.83 Ma). The continuation of this sedimentation rate is
397 supported by the apparent lack of a hiatus or change in lithology through this interval⁶⁸.

398 **ANDRILL-1B**

399 The AND-IB core was drilled in 2006 as part of the ANDRILL McMurdo Ice Shelf Project (Fig. 1), and
400 samples were compiled from published data from the Plio-Pleistocene section of the core¹
401 (Supplementary Data Table 4). Pliocene sediments reflect successions of advance and retreat of the
402 marine-based ice sheet in the Ross Sea, and consist of cycles of diamictite, mudstone and diatomite,
403 bounded by glacial erosion surfaces²⁶.

404 **GDGT processing and analysis**

405 Samples from DSDP 270, CRP-2/2A and DSDP 274 were processed for glycerol dialkyl glycerol
406 tetraethers at the Birmingham Molecular Climatology Laboratory, University of Birmingham. Lipids
407 were extracted from ~10-15 g of homogenised sediment by ultrasonic extraction using dichloromethane

408 (DCM):methanol (3:1). The total lipid extract was fractionated by silica gel chromatography using n-
409 hexane, n-hexane:DCM (2:1), DCM, and methanol to produce four separate fractions, the last of which
410 contained the GDGTs. Procedural blanks were also analysed to ensure the absence of laboratory
411 contaminants.

412
413 Samples were filtered using hexane:isopropanol (99:1) through a 0.4 µm PTFE filter (Alltech part
414 2395), before being dried under a continuous stream of N₂. Samples were then sent to Yale University
415 for analysis. Samples were redissolved in hexane:isopropanol (99:1), and analysed and quantified on an
416 Agilent single quadrupole Liquid Chromatography/Mass Spectrometer (LC-MS) 6100 series using
417 previously established protocols⁷⁵. Due to frequent low abundances of compounds, some samples were
418 re-run at higher concentrations, and integrations derived from these re-runs were favoured. Samples
419 were integrated multiple times and averaged to account for potential integration variation, with an
420 average TEX₈₆ standard deviation of 0.007 between integrations. The areas of individual GDGTs, as
421 well as calculated indices and temperature calibrations are recorded in supplementary Data Table 4.

422
423 Methodology for samples from AND-1B and AND-2A are described in previous works^{11,26}.
424 Unpublished results for samples from CIROS-1 and the McMurdo Erratics were processed and analysed
425 at NIOZ using methods outlined in Schouten et al. (2007). A further 4 previously unpublished results
426 for samples from DSDP 274 (depths 153.63 mbsf, 155.68 mbsf, 163.75 mbsf, 174.2 mbsf) were also
427 added to the compilation. These were extracted using an accelerated solvent extractor, then fractionated
428 by Al₂O₃ column chromatography using hexane:DCM (9:1, v:v), hexane:DCM (1:1) and DCM:MeOH

(1:1). The samples were then dissolved in hexane:isopropanol (99:1, v/v) and filtered over a 0.45- μ m polytetrafluoroethylene filter, before being analysed following procedures outlined in Hopmans et al. (2016). As samples were processed at three different laboratory facilities (University of Birmingham, Yale University and NIOZ), and analysed between two facilities (Yale University and NIOZ), the potential for interlaboratory biases must be considered. Previously reported results from a comparison of 35 laboratories and found that TEX₈₆ and BIT indices were not significantly affected by differences in sediment extraction and processing techniques⁷⁶. TEX₈₆ measurements had an interlaboratory reproducibility for different samples ranging from 0.023 to 0.053, with the differences suggested to be due to instrumental characteristics. The BIT index was found to have good reproducibility at the extremes of the index, where values were close to either 0 or 1, but poorer reproducibility for intermediate values with values typically overestimated. Samples from AND-1B were processed and analysed at both Yale University and NIOZ. Chromatograms of samples analysed in each laboratory were integrated by members of the other for comparison and were found to have an average SST difference of $\pm 0.8^{\circ}\text{C}$, when the TEX₈₆^L calibration⁷⁷ was used²⁶. Four samples processed at Yale University were also analysed at NIOZ with an average SST difference of 0.8°C ²⁶. The results discussed above suggest that while some interlaboratory differences are possible, they are likely to have a minor influence on reported SST values^{26,76}.

446

447 **CO₂ compilation.**

448 The compilation of atmospheric CO₂ concentrations, is based off previous compilations^{47,78,79}, but
449 updated with more recent datasets^{47,79,79–85}. One outlier value of 2622 ppm has been removed at 36.48

450 Ma. Moving averages for CO₂ and temperature datasets were been derived using 'mwStats' in the R-
451 package 'astrochron'⁸⁶.

452

453 **Ice sheet model**

454 Modelling sensitivity tests have previously demonstrated large ice volume differences can result solely
455 from changing topographic boundary conditions through time^{8,39,40,87}. To assess the potential impact
456 topographic changes between the EOT and OMT may have had on oxygen isotope shifts in deep sea
457 records, here we expanded on previous ice sheet modelling experiments of Paxman et al., (2020)⁸ by
458 rerunning selected experiments with an isotope enabled ice sheet model⁸⁸. Experiments run under a steady
459 state climate with an atmospheric CO₂ concentration of 500 ppm and an imposed 5°C warming of the
460 ocean relative to present show a larger AIS ($34.6 \times 10^6 \text{ km}^3$) was in place with an EOT topography relative
461 to experiments with the same climate and an OMT topography, which had a greatly reduced ice volume
462 ($28.9 \times 10^6 \text{ km}^3$), with most of this change occurring in the WAIS. Our isotope enabled simulations suggest
463 that solely due to changes in topography, there would have been a shift in the oxygen isotope composition
464 of seawater of 0.2 ‰. These experiments did not include the Marine Ice Cliff Instability (MICI)⁴¹ and
465 were chosen as they demonstrated the greatest sensitivity to topographic change with the chosen climate
466 forcing. Although beyond the scope of this study we expect that at a lower atmospheric CO₂ forcing and
467 ocean warming there would be comparable (or greater) sensitivity to changes to topography in
468 experiments including MICI.

656 (Bella.Duncan@vuw.ac.nz).

657

658 **Acknowledgements**

659 The authors thank the anonymous reviewers for their helpful feedback which has much improved the
660 paper. We are grateful for access to samples from the IODP core repository at Texas A&M University
661 for DSDP Sites 270 and 274, and to the Alfred Wegener Institute for access to samples from the Cape
662 Roberts Project. This study was funded via an Antarctica New Zealand Sir Robin Irvine PhD
663 Scholarship and Scientific Committee of Antarctic Research Fellowship awarded to B. Duncan, with
664 additional funding by the Royal Society Te Apārangi Marsden Fund award MFP-VUW1808, and the

665 New Zealand Ministry of Business Innovation and Employment through the Antarctic Science Platform
666 (ANTA1801), and Contract C05X1001. The Natural Environment Research Council funded J. Bendle
667 (Standard Grant Ne/I00646X/1). D. Kulhanek was supported by US National Science Foundation award
668 OCE-1326927. The authors are grateful for support from IODP and support in kind from the University
669 of Birmingham and Yale University. We thank Stefan Schouten (NIOZ) for laboratory support and
670 assistance with temperature data, and James Super for assistance with sample analysis while at Yale
671 University.

672

673 **Author contributions**

674 B.D, R.M., J.B., R.L. and T.N. designed the research. B.D. processed samples for DSDP 270, DSDP
675 274 and CRP-2/2A. S.K. conducted analysis on DSDP 270, DSDP 274 and CRP-2/2A. F.S. processed
676 samples and conducted analysis on AND-2A. F.H. processed samples and conducted analysis on
677 additional samples for DSDP 274. V.W. processed samples and conducted analysis on AND-1B,
678 CIROS-1 and the McMurdo Erratics. C.W. processed samples and conducted analysis on AND-1B. J.P.
679 and C.C. developed the age model for CIROS-1. S.M. contributed statistical analyses. E.G. provided ice
680 volume model output and advised on interpretation. T.D.J. assisted with temperature calibration
681 interpretations. D.K.K. and C.K. assisted with sedimentological and environmental interpretations for
682 DSDP 270. H.M. advised on laboratory processing and data interpretation. G.T.V. advised on GDGT
683 data interpretation. B.D. created the figures and wrote the text with assistance from all authors, in
684 particular R.M., J.B., R.L. and T.N.

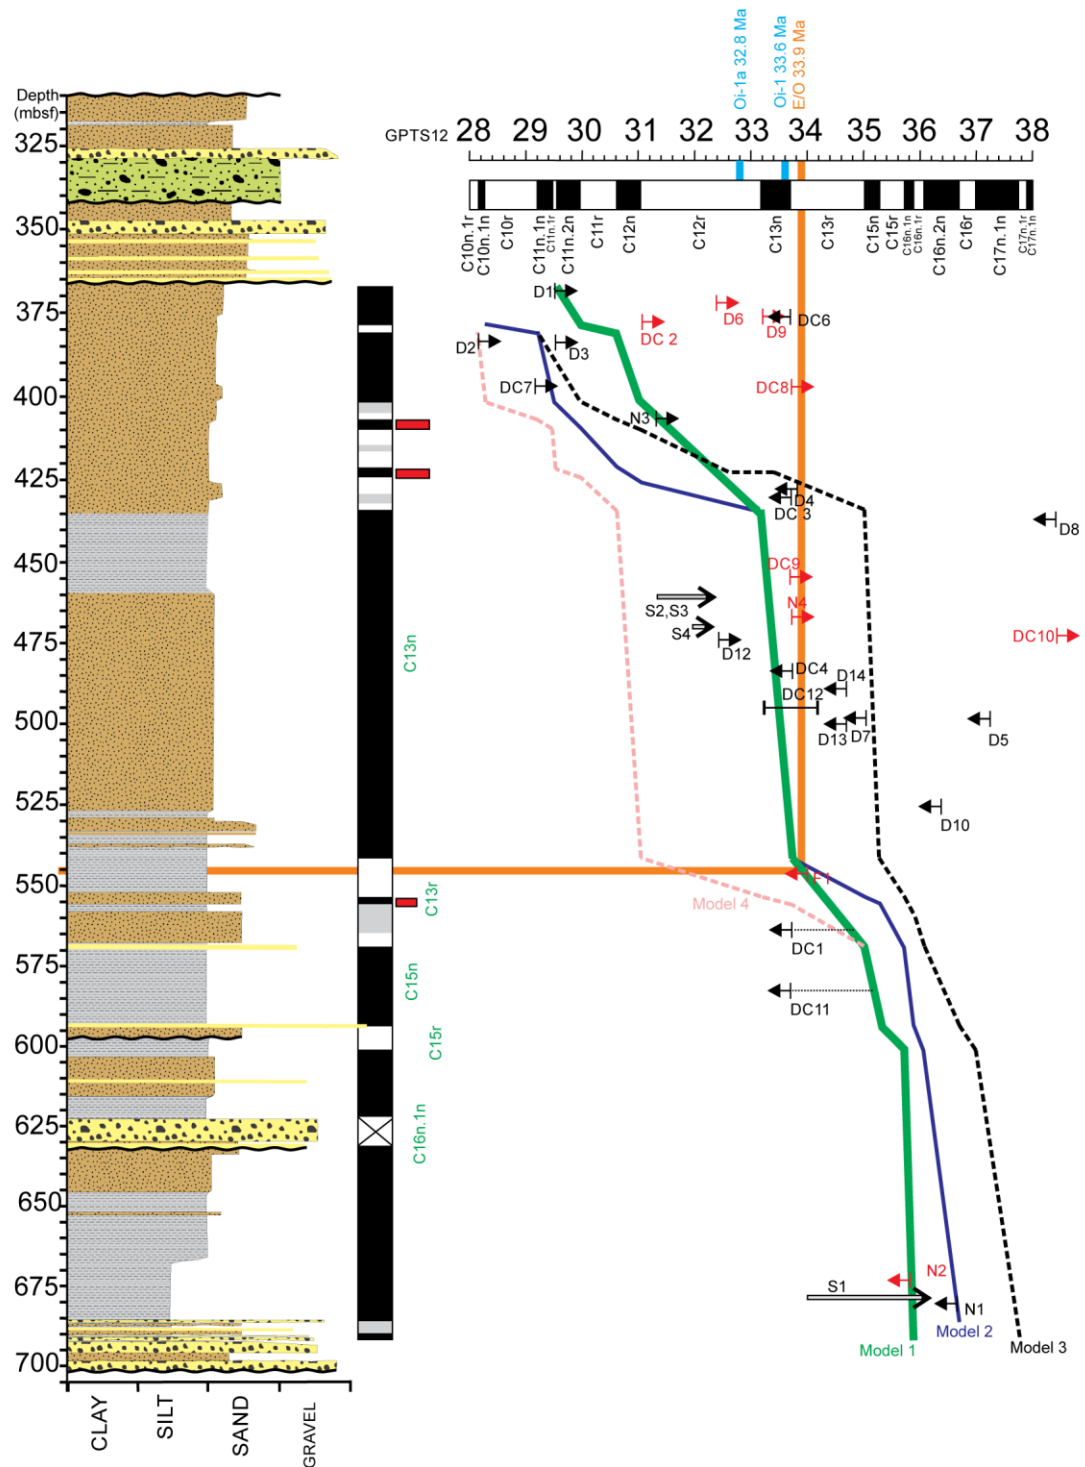

685

686 **Data Availability**

687 Data sets generated during and/or analysed during the current study are available in Supplementary

688 Data Tables 1-4.

689

Extended Data Figure 1. Age model for CIROS-1, based on the paleo-magnetic record from Wilson et al. (1998) and new biostratigraphic events described in Supplementary Data Table 1. The preferred age model is shown in green (model 1), as described in Methods section.
