13 **Abstract**

14 The onset of prehistoric farming brought unprecedented changes to landscapes and their
15 biodiversity. Past biodiversity patterns are broadly understood for different parts of Europe,
16 and demonstrate trajectories that have been linked to prehistoric and historic demographic
17 transitions, and associated land-use practices. To our knowledge, this paper is the first
18 attempt to directly link evidence of agricultural practice from the archaeological record to
19 biodiversity patterns. Records of fossil pollen are used to estimate plant and landscape
20 diversity patterns, and novel approaches are employed to analyse 1194 harmonised
21 archaeobotanical samples (~~charred~~-plant macrofossil remains) spanning the prehistoric and
22 Roman periods, from an area in the south-east of England. We demonstrate changes in the
23 use of crops and gathered edible plants and non-linear trends in cultivation practices.
24 Whilst, overall, cereal production is characterised by ever larger and extensive regimes,
25 different trajectories are evident for most of early prehistory, the Middle Iron Age and the
26 Late Roman period. Comparisons with the Shannon diversity of fossil pollen records from
27 the same region suggest a positive relationship between developing agricultural regimes
28 and landscape scale biodiversity during the prehistoric period. The Roman period represents
29 a tipping point in the relationship between expanding agriculture and pollen diversity, with
30 declining pollen diversity evident in the records from the region.

37

38 1.Introduction

39 Biodiversity is inextricably linked to landscape type and stability. Climate change, human
40 population densities and farming have been major forces that have had an impact on
41 observable early Holocene levels of biodiversity (Redford and Richter, 1999; Giesecke et al.,
42 2019). The latter two factors are interdependent as larger populations necessarily require
43 increased food production, although it has been shown that population growth does not
44 have a predictable, linear impact on vegetation and insect diversity (Woodbridge et al.,
45 2021). How land was used for food production and the different time scales involved in
46 species regeneration need to be considered when interpreting the effects of land use (Watts
47 et al., 2020). Climate change is known to have influenced livelihoods and stages of climatic
48 shifts in prehistory have been linked to population “booms” and “busts”, adaptations in
49 farming practices, and changes in land cover (Woodbridge et al., 2014; Bevan et al., 2017).
50 The Birks et al. (2016) conceptual model on trends in biodiversity during the Holocene in
51 north-west Europe describes how, within fertile soils, woodland clearance for farming had a
52 positive effect on biodiversity through the creation of new habitats. This beneficial effect
53 lasted until a tipping point was reached, after which continued woodland clearance/land
54 use had a detrimental impact upon biodiversity (see also Woodbridge et al., 2021: Fig.1). It
55 remains unclear when the tipping point was reached, and whether this was within
56 prehistory (e.g. with the development of spatially-extensive enclosures (cf. Løvschal 2020))
57 or as a consequence of the rapid onset of mechanised agriculture in the past 200 years (Ellis
58 2019).

59 From the onset of farming ~~across Britain and Ireland in the British Isles~~ at c.4000 BC,
60 vegetation cover has gradually, though not continuously, become more open (Fyfe et al.,
61 2013, 2015; Trondman et al., 2015). A similar pattern is evident in the diversity and
62 evenness of fossil pollen (as a proxy for vegetation change) from the south-east of England,
63 which show a continued increase in diversity between the Bronze Age and the Roman
64 period (Woodbridge et al., 2021: Fig.4). Entomological remains from archaeological sites
65 also indicate changes in habitats through time (Smith et al., 2019, 2020). The presence of
66 synanthropic insect species in Britain increased during early prehistory and taxa associated
67 with pastoral activities were common during the Bronze and Iron Ages. Changes in insect
68 taxa are also associated with the Romanisation of Britain, such as new grain pests indicating
69 denser human settlements and increased agricultural production (Smith et al., 2019, 2020).

70 In this paper we explore how arable production, evidenced from ~~charred~~ remains of crops,
71 seeds and fruits, changed from its onset in the Neolithic to the Late Roman period and
72 whether such changes coincide with landscape diversity trends inferred from fossil pollen
73 records. ~~The Saxon period is not included as its arable farming regimes have been subject to~~
74 ~~detailed investigations (McKerracher, 2018, 2019; McKerracher and Hamerow, 2022).~~
75 Amalgamating data by archaeological period allows general trends in farming practices to be
76 explored and compared to contemporary off-site fossil pollen records. With the aid of
77 multivariate analyses and the ecological signatures of arable weeds, trends in farming
78 practices are identified. Whilst these are common approaches in archaeobotany (De

79 Vareilles et al., 2021), we are not aware of direct comparisons with fossil pollen records, or
80 studies that attempt to explain how land use drove biodiversity over long time scales. This
81 research therefore represents a novel and important contribution to how we understand
82 the relationship between land use, land cover and biodiversity. The research area covers the
83 region of southern England south of the Thames, excluding the Southwest region other than
84 a cluster of Neolithic sites in Wiltshire close to the border with Hampshire (Fig.1). This area
85 contains some of the earliest farming sites in Britain and all periods are well represented in
86 the archaeobotanical record.

87 Whilst acknowledging that cause and effect between climate, farming practices and
88 biodiversity are complex and convoluted, the integration of two archaeological and
89 palaeoecological strands of evidence represents a fundamental and important step to
90 demonstrate, for the first time, how a better understanding of land-use practices can
91 contribute towards explaining changes in land cover and biodiversity.

92

93 **2. The development of agriculture in England, with a focus on the south-east**

94 The introduction of farming in Britain and Ireland instigated localised and small-scale
95 deforestation of deciduous woodlands (Fyfe et al., 2013; Woodbridge et al., 2014). Land-
96 cover changes correspond well to the summed probability distribution (SPD) of radiocarbon
97 dates which suggest a demographic incline during the ENEOL (Bevan et al., 2017: Fig. 1;
98 Shennan et al., 2013: Fig.3). Indeed, the correlation between the arrival of farmers and the
99 decline in deciduous woodland has been shown to be statistically significant (Racimo et al.,
100 2020; see also Marquer et al., 2017). The restricted range of Neolithic arable weeds,
101 predominantly annuals, point to permanent plots more than shifting cultivation (eg: Jones
102 and Rowley-Conwy, 2007). Isotopic analyses on cereal grains from six sites across central
103 England and Wales suggest both intensive (site in Derbyshire: Bogaard et al., 2013) and
104 extensive (sites in Wales: Treasure et al., 2019) regimes were practised.

105 A dramatic change in agricultural practice across most of Britain and Ireland is evident from
106 the start of the Middle Neolithic (c.3300 BC). Pollen records point to a regeneration of
107 deciduous woodland (Treasure et al., 2019; Whitehouse et al., 2014) with an associated
108 decline in vegetation diversity. Trends in the SPD of dates on cereal grains show a sharp
109 decline across England, as opposed to the number of dates on hazelnut shells, suggesting
110 that gathered nuts continued to be used whilst the cultivation of cereals was greatly
111 reduced, and even stopped altogether in some regions, such as the south-east of England
112 (Bevan et al., 2017; Stevens and Fuller, 2012, 2015). The rarity of cereals in later Neolithic
113 assemblages has long been recognised (e.g. Brown, 2007; Jones, 1980, Moffett et al., 1989;
114 Robinson, 2000), even though animal domesticates, particularly cattle, continued to be an
115 important dietary element (Serjeantson, 2011). A transition from mainly fixed, agricultural
116 communities to a reduced population of mobile pastoralists is therefore likely (Rowley-
117 Conwy et al., 2020; Worley et al., 2019). The shift in lifestyle and decline in human
118 demographics may have been triggered by unstable, colder and wetter climatic conditions
119 (Bevan et al., 2017; Stevens and Fuller, 2015; Whitehouse et al., 2014). Additionally, crop

120 pests and diseases could have contributed towards agricultural collapse (Antolín and
121 Schäfer, 2020; Dark and Gent, 2001). A deterioration in soil quality has also been suggested,
122 as a focus on a narrow range of cultigens by an increasing population may have led to soil
123 depletion and harvest failures (Colledge et al., 2019; Shennan et al., 2013).

124 The Beaker period is marked by a new influx of people of central European ancestry by
125 around 2400 BC (Olalde et al., 2018). Changes in material culture, such as the introduction
126 of Bell Beaker pottery, and settlement patterns also attest to a shift in lifestyles (Bradley,
127 2019: chapter 4). Little is known of Beaker subsistence strategies, primarily due to the lack
128 of settlement sites, although a study of the isotopic signatures in human bone suggests a
129 diet high in terrestrial animal protein with steadfast consistency across Britain (Parker
130 Pearson et al., 2016). The latter study also evidenced a high degree of mobility within
131 Britain, supporting the idea that subsistence strategies continued to be based upon
132 predominantly pastoral lifestyles (Bevan et al., 2017). The Beaker period is also marked by
133 the expansion of Neolithic monuments, requiring a greater gathering of labour and
134 organisation than previously seen (Gibson, 2020).

135 The resurgence in arable agriculture at around 1600 BC has been termed the Middle Bronze
136 Age agricultural revolution (Stevens and Fuller, 2012), and is associated with renewed and
137 repeated migrations from the European continent (Patterson et al., 2022). Fossil pollen
138 records indicate a sharp decrease in woodland cover (Woodbridge et al., 2014), which
139 coincide with the development of field systems and drove-ways, particularly in southern and
140 eastern Britain (Bradley et al., 2016; Yates, 2007). The latter are suggestive of an inclusive
141 use of enclosures, perhaps on a seasonal rotation system, to benefit crops and farm
142 animals, as well as disturbance-tolerant weeds. Indeed, the increase in grassland perennials
143 during the LBA is indicative of the cultivation of fields that had previously been under
144 pasture (Stevens and Fuller 2018: 31). Spelt is a hardier wheat than emmer and its adoption
145 from the MBA has been argued to reflect a change to more extensive arable cultivation (Van
146 der Veen and Palmer, 1997). The change in regime is thought to have been in response to a
147 need for increased cereal production and the quantity and type of farm animals (Van der
148 Veen, 2016: 302). The Bronze Age in southern Britain sees a rise in sheep at the expense of
149 cattle (Hambleton, 2008: 56), animals which cannot provide the same level of manuring or
150 be used to plough fields. It is likely that spelt was initially mixed with emmer, but that, as a
151 result of demographic growth, changes in animal husbandry, its greater adaptability to
152 poorer growing conditions and its higher yielding capacity, spelt became the dominant
153 cereal (Lambrick with Robinson, 2009: 258; Van der Veen, 1995: 342; 2016: 301-302).|The
154 Bronze Age agricultural intensification is also evident from agricultural tools and features,
155 such as granaries (Bradley et al., 2016). Wells and waterholes enabled farmers to settle
156 away from main waterways in permanent settlements, thereby expanding the agricultural
157 potential of landscapes (Yates, 2007: 34), and increasing habitat diversity further inland.
158 Insects chart a change from mostly wooded landscapes during the Neolithic and EBA, to
159 open ground associated with pasture and fodder production during the later Bronze Age
160 and Iron Age (Smith et al., 2019, 2020).

Commented [DVA1]: Remove?

161 Britain became more insular towards the end of the LBA, with limited evidence for foreign
162 contacts from both archaeological and palaeogenomic evidence (Cunliffe, 2013; Patterson
163 et al., 2022). A population decline (Bevan et al., 2017) would have led to reduced arable
164 production and the abandonment of settlements/fields. In southern England, the MIA is a
165 period of significant social change, with the emergence of multivallate hillforts
166 encompassing a greater catchment area, indicating a level of social cohesion and
167 organisation not witnessed in the preceding era and an increased political, or at least
168 communal, control over land use (Jones 1985, 1996, 2008). Hillforts were abandoned by the
169 LIA and a change in land use is once again visible with the scattering of settlements and new
170 agricultural developments (Cunliffe, 1994, 2013).

171 The Iron Age weed spectrum in central and southern Britain became surprisingly uniform,
172 perhaps indicating that by the LIA agricultural regimes became more influenced by rising
173 market forces or a standardisation in crops and agricultural tools, than by local conditions
174 and choices (Campbell, 2017; Carruthers and Hunter Dowse, 2019: 55). Frequent wild oat
175 and brome grass are assumed to have been an accepted addition to the crop (Knörzer,
176 1967; Zech-Matterne et al., 2021), whilst ryegrass might have been an early fodder crop
177 around Danebury (Campbell, 2000; see also Lodwick, 2017). Other common weeds include
178 small grasses, vetches/tares, cleavers and clover types (clover, medicks, trefoil), and are
179 suggestive of the use of grass fallow in a rotation regime (Carruthers and Hunter Dowse,
180 2019: 55). They are also indicative of a full annual agricultural regime, with crops sown in
181 both autumn and spring. An increase in oat (*Avena* sp.) grains and awns is suggested to
182 represent the LIA cultivation of this potential cereal (Campbell, 2000; Campbell and Straker,
183 2003). Oat and pea indicate spring sowing, a practice which may have led to growing spelt
184 (in autumn) and spring barley as monocrops rather than as a mixed crop (Campbell and
185 Hamilton, 2000).

186 Agriculture in southern England during the Roman period is characterised by large-scale,
187 extensive regimes focused on growing spelt wheat (Allen and Lodwick, 2017; Campbell,
188 2017; Lodwick et al., 2020). Production was scaled-up to feed a growing population, a large
189 army and even export grain to the continent (Allen and Lodwick, 2017; Orengo and Livarda,
190 2015; Van der Veen, 2016). The Roman period also saw an increase in horticulture and
191 imports, making it sometimes difficult to separate locally grown from imported plant foods
192 (cf. Van der Veen, 2014). Developments in ploughing technology, such as asymmetrical
193 shares, first seen during the LIA, allowed the expansion of cultivation onto new, heavier soils
194 (Jones, 1985, 2009). However, Roman technology is likely to have been restricted to the
195 more Romanised settlements as it was not until the later Saxon and medieval periods that
196 'Roman' weeds became prolific (Allen et al., 2017; Stevens and Fuller, 2018: 33).

197 During the fall of the Roman Empire a reduction in arable production is traditionally
198 associated with a population decline in Britain, though the dynamics between agricultural
199 production and the changing political and social spheres remains elusive (Van der Veen,
200 2022). The starkest contrast between Romano-British and Anglo-Saxon cereal production is
201 the almost complete replacement of spelt for free-threshing wheat (McKerracher, 2018;
202 Van der Veen, 2022). The latter is usually considered a crop-contaminant in Roman samples,

203 though its cultivation may have begun as small-scale productions to produce more refined,
204 white bread for the elite (Van der Veen, 2022: 324-326).

205

206 **32. Materials and Methods**

207 32.1 Archaeobotanical dataset

208 Neolithic to rural Romano-British archaeological sites with records of archaeobotanical plant
209 macrofossils (cereal grains and chaff, pulses, fruits, and nuts and seeds of wild plants) were
210 selected from the research area. Data collection was focused on records available online
211 which are biased towards large-scale development projects, such as the Channel Tunnel Rail
212 Link (Fig. 1). As early prehistoric samples tend to be sparser, greater focus was spent finding
213 records from these periods. All plant macrofossils were registered by site in ArboDat 2016
214 English Version © (Kreuz and Schäfer, 2002), an Access database which associates each
215 taxon with its plant part (e.g. seed, spikelet, awn), level of identification (genus, species, cf.
216 species), preservation status (charred, waterlogged, mineralised), sample volume and
217 flotation mesh size. Each site record has a unique ArboDat reference code (Table 1): these
218 data will be made open access through the Archaeological Data Service. A dataset of 1718
219 archaeobotanical samples from 110 sites have been added to the ArboDat database.

220 To explore changes in land use from the Early Neolithic (ENEOL) to the Late Roman (~~LRO~~)
221 period (LRO), the complete archaeobotanical dataset was filtered to remove:

- 222 • waterlogged plant macro-remains (carbonised, mineralised and silicified remains
223 were retained. The latter two make up <5% of total counts and presence by period,
224 and all species are also present in a carbonised state);
- 225 • taxa that are unlikely to represent edible plants or arable weeds, such as trees and
226 shrubs with non-edible fruits, heather and ferns;
- 227 • unquantifiable plant parts, such as awns, glume fragments, culms, thorns and non-
228 tuberous roots (edible roots of pignut (*Conopodium majus*) and roots of false oat
229 grass (*Arrhenatherum elatius*) ~~grass~~ were retained though the former were found to
230 be rare);
- 231 • indeterminate remains and taxa identified to cf. family (e.g. cf. Ranunculaceae
232 (Chenopodiaceae/Caryophyllaceae and Polygonaceae/Cyperaceae were retained);
- 233 • items not dated to the early, middle or late span of an archaeological period, either
234 directly or by association. Dates and periods follow Historic England's Period List,
235 FISH terminology (Updated March 2022: [http://www.heritage-](http://www.heritage-standards.org.uk/chronology/)
236 [standards.org.uk/chronology/](http://www.heritage-standards.org.uk/chronology/)).

237 The filtering process resulted in archaeobotanical data from 1194 samples (93 sites) used in
238 this study (Fig.1, Table 1). In order to further harmonise the data, taxa identified to possible
239 species (e.g. *Apium* cf. *nodiflorum*) were recorded as species. Identifications to possible
240 genus were either retained at genus level or recorded to family level, depending on seed
241 morphology and ecological grouping. For example, cf. *Rubus* was recorded as *Rubus* because
242 all British species grow under similar conditions, are edible and are distinct from other

243 Rosaceae seeds, whereas cf. *Danthonia* was recorded as Poaceae since small grass seeds are
244 difficult to separate taxonomically. The mode value of 10 litres was used as a conservative
245 estimate for missing sample volumes (bulk-~~soil~~ samples from archaeological deposits). Only
246 the estimated volumes for the Early Roman Period (ERO) made up >10% of the total volume
247 (14.5%). Although crop densities per period may have been artificially increased, using the
248 mode value of 10 Litres makes it unlikely that the actual densities differ substantially (Table
249 2).

250 The number of samples and the number of identified archaeobotanical remains varies
251 considerably between contemporary sites as well as archaeological periods (Table 2).
252 Inconsistencies also exist in the recording of contextual provenance, with many reports
253 containing poorly defined or missing information. To mitigate against these biases when
254 comparing archaeological periods, all data were amalgamated by period regardless of
255 context and all analyses were produced using presence/absence data, except for Figure 4.
256 Transforming count data to a binary format has enabled us to include estimated as well as
257 unusually large counts and to avoid apparent differences between periods based on seed
258 count, which can reflect the scale of cereal processing and the use/discard of processing
259 waste (Fuller et al., 2014) relate primarily to changes in the management of cereal
260 processing by products. Presence/absence data also reduces potential biases towards
261 particular arable weeds and their associated ecological conditions; taxa may be more
262 numerous in assemblages either because they produce more seeds or because they are
263 retained with crops until the last stages of processing and are therefore more likely to
264 become burnt as settlement waste (Hillman, 1984).

265 Figure 4b uses whole counts of plant macroremains and sample volumes to illustrate
266 changes in assemblage concentrations by period. Although changes in assemblage densities
267 reflect changes in settlement patterns and the organisation of crop processing/use, they are
268 also associated with the growth of populations and are here used as a crude measure for
269 the scale of production. The density of assemblages is plotted against the trend in pollen
270 diversity (Shannon index H), further explained in section 3.2. The relationships between
271 trends were tested using Spearman's Rank, which shows a positive correlation between
272 pollen diversity and concentrations of crop remains (Spearman's rho = 0.6 and $r^2 = 0.5$,
273 $p < 0.005$).

274 Figure 1: The location of off-site pollen cores (b, colours represent site groups) and on-site
275 archaeobotanical samples (c) used in this study. Note that S-site numbers refer to Table 1.
276 References to the pollen cores are listed in the supplementary information, Table 1.

286

287 Table 2: Summary data of the charred-plant macrofossils by archaeological period. Counts
 288 are taxa present in ≥5% (<5%) of samples per period (for the EBA and the weeds of the
 289 Beaker period (n) is the number of taxa in only one sample); *Identifications to family and
 290 genus levels were only counted when more precise identifications were not present

291

292 3.2.1.2 Ecological analyses

293 Seeds of herbaceous wild plants are here analysed as arable weeds. Whilst some may
 294 represent species that were eaten or used (as leaves, roots, etc), their presence as charred
 295 seeds associated with cereal grains/chaff suggests they grew in arable fields. An
 296 autoecological approach, based on modern field observations of individual species'
 297 tolerances to environmental conditions, was adopted for the ecological analysis of the data
 298 gathered for the study region (see De Vareilles et al., 2021 for a critique of different
 299 ecological approaches to the analysis of on archaeobotanical material). The approach was
 300 first developed by Heinz Ellenberg, in which he measured plants' preferences to
 301 environmental gradients in Central Europe, using a 9-point scale (Ellenberg, 1988; Ellenberg
 302 et al., 1991). Ellenberg numbers, or indicator values, were first defined for, and applied to,
 303 the flora of Central Europe, but are now also available for British plants (Bunce et al., 1999;
 304 Hill et al., 1999, 2000). Adjusted Ellenberg numbers have been adjusted for British plants
 305 (Bunce et al., 1999; Hill et al., 1999, 2000), and have been used to record species'
 306 preferences for soil nitrogen (-2-3 = low, 4-5 = intermediate, 6-7 = high, 8-9 very high
 307 fertility) and light intensity (6 = shade to well lit, 7 = mostly well lit, 8 = ample light)
 308 (Fig. 5a&b&c&d). Figure 5a, b and c illustrates species' life form (annual or perennial),
 309 preference to light or heavy soils and flowering habit of annual plants (Fitter et al., 1994;
 310 Online Atlas of British and Irish Flora). The onset and duration of flowering in annuals is
 311 associated with both the season of germination and a plant's tolerance to disturbance
 312 (Bogaard et al., 1999, 2001; Hodgson and Grime, 1990). Plants that flower early are more
 313 likely to develop in autumn-sown crops, growing in time with the crop. Similarly, plants that
 314 germinate and flower late are at a competitive advantage in spring-sown crops, where they
 315 avoid competition from autumn-germinating plants and the spring plough. Some annuals
 316 flower repeatedly throughout the year as an adaptation to disturbance, and- duration of
 317 flowering time can therefore be used as an indication of disturbance frequency. Figure 5c
 318 translates flowering onset and duration habit to season of germination and disturbance
 319 levels following Bogaard et al. (2001)-Table 3). The ubiquity charts in Figure 5 are calculated
 320 using presence/absence data per sample, not the number of taxa or seeds. Relevant taxa
 321 within a given sample (i.e. all those with a score for a particular ecological/biological trait)
 322 are reduced to a single occurrence by score. The number of samples is that for which there
 323 is information on a given trait. The ubiquity scores by archaeological period are therefore a
 324 measure of the frequency of presence of a particular characteristic within an assemblage for

325 an ecological/biological trait. The measured characteristics for each species are listed in SM
326 Table 2.

327 3.2.1.3 Data analyses

328 Within this study, several approaches are used to explore the archaeobotanical dataset for
329 patterns of changing land use. As the number of samples varies between archaeological
330 periods, we tested the relationship between plant taxa richness and the number and
331 volume of samples. Both correlations are moderate, with Spearman's Rho centred around
332 0.6 and r^2 around 0.3 ($p < 0.0005$ in both cases). Similar results are found when the
333 correlations are calculated by individual time periods, except for the Beaker and Early
334 Bronze Age (EBA) where correlations are weak (Rho=0.3/0.2 respectively, $p=0.3$). The latter
335 confirms that the distribution and recovery of Beaker and EBA archaeobotanical finds are
336 unpredictable, making it even more important to sample sites from these periods
337 intensively. Despite variations in site types and sampling strategies, taxa richness is
338 comparable in other periods, validating comparisons made below.

339 The presence of crops and gathered edible plants/foods per sample across the whole dataset
340 was plotted using ubiquity of taxa by for all archaeological periods, to illustrate the changing
341 use of plant foods through time (Fig.2). The same charts are used to present biological and
342 ecological values. The internal structure of the dataset was explored using two multivariate
343 ordination techniques: correspondence analysis (Smith, 2014) was initially attempted but, as
344 distinct clusters were not evident (see supplementary information Fig.1), hierarchical cluster
345 analysis (HCA, Fig.3) was used (Murtagh and Legendre, 2014; Ward, 1963). Both were
346 performed in the 'Vegan' R package (Oksanen et al., 2020), after small samples and rare taxa
347 had been removed, i.e. samples with fewer than 30 items (before the transformation to
348 presence/absence data) and taxa occurring in fewer than 2% of samples ($n=24$). Excluding
349 small samples affected the early prehistoric periods most strongly, removing two thirds to
350 three quarters of the Middle/Late Neolithic, Beaker and EBA samples. HCA groups samples
351 by similarity of composition and visual inspection of outputs and experimentation with
352 different grouping levels suggested that six clusters adequately represent relationships of
353 dissimilarity between different groups. This ordination technique is more commonly used in
354 the field of palynology (e.g. Woodbridge et al., 2018), but has the advantage over
355 Correspondence Analysis of allowing the taxonomic composition of each cluster to be
356 explored as well as a taxon's frequency based on the cluster group assigned to each sample.
357 Taxa that occurred in more than $\geq 50\%$ of samples within a cluster were identified and are
358 here described as 'common' (Table 3).

359

360 3.2.2 Fossil pollen data

361 The fossil pollen datasets used in this study include 106 datasets from the south-east of
362 England (Woodbridge et al., 2021; in review) (Table SM1). Pollen records (Fyfe et al., 2013;
363 Leydet et al., 2007-2020; Trondman et al., 2015) from individual coring sites have been
364 taxonomically harmonised and summed into 200-year time windows (Woodbridge et al., in
365 review). Shannon diversity indices derived from the pollen datasets, which reflect both taxa

366 richness and evenness, are presented in Fig. 4. Quantified land cover was reconstructed
367 from a subset of 98 sites suitable for the application of the REVEALS (Regional Estimates of
368 Vegetation Abundance from Large Sites) approach (Fyfe et al., 2013; Githumbi et al., 2022;
369 Marquer et al., 2014; Sugita, 2007). This approach uses information about the productivity
370 of different plants, the dispersal behaviour (fall speed) of different pollen types, and the site
371 type (lake or peatland/bog) and size to quantify land cover using pollen count data. To
372 produce estimates of regional vegetation using the REVEALS model, pollen sites need to be
373 grouped together. This grouping is based on site type, site size, proximity to other pollen
374 sites, and landscape characteristics. The grouping resulted in five sub-regions in SE England,
375 which are illustrated in Fig. 1b (see Woodbridge et al., in review, for further details). A
376 pairwise Wilcoxon test for non-normally distributed data was used to test the differences
377 between pollen diversity scores by archaeological period. All comparison periods were
378 shown to be statistically significantly different with a p-value below 0.05~~Sites have been~~
379 ~~grouped into sub-regions according to location and site characteristics (see Woodbridge et~~
380 ~~al., in review, for further details).~~

381

382 **4.3. Results**

383 Figure 2: The ubiquity of crops (a), fruits and nuts (b) by archaeological period. Only taxa
384 present in >5% of samples in at least one period are represented. Pulses includes *Lens*
385 *culinaris*, *Pisum sativum*, *Vicia faba* and large Fabaceae; cabbage/mustard includes *Brassica*
386 *nigra/oleraceae/rapa* and Brassica/Sinapis; berry includes *Rubus* spp.; *Prunus* includes
387 *Prunus* spp., and acorn all *Quercus* spp. Keep 2a. Change graph to include oat, etc. Avena sp.
388 may include undomesticated grains.

389 3.4.1.2 The representation of crops, arable weeds and edible fruits and nuts (Fig.2, Table 2)

390 Spelt wheat (*Triticum spelta*) and hulled barley (*Hordeum vulgare vulgare*) became the main
391 crops in Britain during prehistory and the Roman period. The trends in ubiquity suggest an
392 overall temporal increase in the range and presence of crops across sites (Fig.2a). The trend
393 mirrors that of the density of assemblages, showing that crop waste became more
394 numerous and frequent. Exceptions to these trends are evident for the Middle to Late
395 Neolithic (M/LNEOL), Beaker, Middle Iron Age (MIA) and the LRO. The drop in cereal
396 remains in the M/LNEOL and Beaker periods is counteracted with a marked increase in two
397 gathered resources: hazelnut and apples/pears (*Malus/Pyrus*). Compared to the Early Iron
398 Age (EIA), the MIA sees a marked drop in the ubiquity of barley but an increase in that of
399 emmer (*T. dicoccum*) and pulses. The decline in the ubiquity of crops is less marked for the
400 LRO: a decline is visible for emmer, spelt and pulses though the score for free-threshing
401 wheat (*T. aestivum/durum/turgidum*) increases.

402 The prevalence of wheat (*Triticum* sp.) and barley (*Hordeum vulgare*) over other crops is
403 visible throughout the archaeological periods, but the relative proportion of barley to wheat
404 is not constant. Barley is tolerant of poorer growing conditions, both edaphic and climatic,
405 and was an important animal feed (Rhiel, 2019). Whether the changing relative
406 representation of barley is associated with changes in climate or animal husbandry cannot

407 be fully explored here, although these two factors will certainly have influenced arable
408 agriculture. Naked barley (*H. vulgare* var. *nudum*) is infrequent and only present in the early
409 prehistoric samples, as is the pattern across the British Isles/United Kingdom and Europe
410 (Lister and Jones, 2013).

411 Naked/free-threshing cereals are less visible in the charred archaeobotanical record since
412 the grains are less likely to adhere to any surrounding chaff and require less processing
413 (Hillman, 1984). Free-threshing wheat (*T. aestivum/durum/turgidum*) is most frequent in
414 the Neolithic (n=193, 3% of all wheats) and Roman (n=398, 0.04% of all wheats) samples,
415 although the number of remains are low. Rare grains and chaff of tetraploid free-threshing
416 wheat from Thanet Earth (site 78) were radiocarbon dated to 3940-3660 cal. BC (Carruthers,
417 2019). Conversely, other grains from Neolithic contexts have consistently returned medieval
418 and later dates indicating that their presence is intrusive (Pelling et al., 2015). The richest
419 assemblage was recorded from late Roman samples at Grateley (site 35) and consists of 121
420 free-threshing wheat grains but only three rachises, amongst thousands of hulled barley and
421 spelt wheat (*T. spelta*) remains. The dataset corroborates current evidence suggesting that
422 free-threshing wheat was not a common crop in Britain before the Anglo-Saxon period
423 (McKerracher, 2018). Similarly, rye (*Secale cereale*) does not appear to have been regularly
424 cultivated in Britain until after the Roman period as it occurs in less than five percent of
425 samples per period (cf. Behre, 1992). Cultivated oat (*Avena sativa*) is also poorly
426 represented in the dataset, its highest occurrence being in the Middle (MIA) and Late (LIA)
427 Iron Age (in 3% of samples). However, domesticated oats are difficult to identify without
428 their chaff and are likely to be under-represented in Iron Age and Roman samples, where
429 oat caryopses recorded as *Avena* sp. are present in 40% to 58% of samples per period.

430 The likelihood of intrusive or residue cereals, particularly in Middle to Late Neolithic
431 (M/LNEOL), Beaker and EBA samples, which tend to contain very few remains, makes
432 interpretations difficult. For example, in contrast to the ENEOL, when emmer wheat (*T.*
433 *dicocum*) is well represented, the dataset contains only one grain positively identified to
434 species in the M/LNEOL. Emmer wheat was part of the original suite of domesticated cereals
435 whilst European spelt (*T. spelta*) developed after farmers had settled in central Europe,
436 where it became widespread during the Bronze Age (Blatter et al., 2004; Zohary et al., 2012:
437 49-50). The earliest British record of spelt is from Monkton Road (site 52) where glume
438 bases, associated with fragments of Celtic bean (*Vicia faba*), were dated to the end of the
439 EBA (1896-1690 cal BC, Martin et al. 2012). Figure 2 clearly shows how spelt became the
440 predominant wheat in the region by the Early Iron Age (EIA).

441 Early prehistoric finds of cultivated pulses (see Fig. 24 for taxa included in this category)
442 should also be viewed with caution as all directly dated finds from Neolithic contexts pertain
443 to later periods (Pelling et al., 2015; Stevens and Fuller, 2012; Treasure and Church, 2017).
444 Celtic beans first appear during the EBA, becoming more prolific along the south coast and
445 spreading inland from the Middle Bronze Age (MBA) onwards (Treasure and Church 2017).
446 Evidence for pea (*Pisum sativum*) is rarer. Its presence at the Thanet pipeline excavations
447 (sites 17, 18 and 77), along with emmer, spelt, barley and Celtic bean provides evidence for
448 one of the first more complex husbandry regimes in British prehistory (Stevens 2009). The

449 absence of pulses in the dataset from EIA samples is surprising, but reminiscent of a national
450 pattern: pulses and flax were not universally grown during the Iron Age, perhaps reflecting
451 regional cultivation of pulses in areas of poorer soils and the growth of fodder crops (de
452 Carle, 2014: 160; Treasure and Church, 2017: 120). The frequency of pulses increases during
453 the Roman period, when the only secure find of lentil (*Lens culinaris*) is recorded (site 71),
454 although potentially imported. The drop in the ubiquity of pulses during the LRO may reflect
455 a decline in trade rather than/as well as cultivation.

456 Flax (*Linum usitatissimum*) was grown for both its fibre and oily seeds and evidence for the
457 former is confirmed by Bronze Age waterlogged deposits of retting fibres (Carruthers and
458 Hunter Dowse, 2019: 42). As with cabbage/mustard and opium poppy seeds (*Papaver*
459 *somniferum*), the size and oily nature of flax seeds inhibits their survival to charring and
460 archaeological recovery. Nevertheless, large assemblages, such as the 509 seeds recovered
461 from MBA Weir Bank Stud Farm (site 85) confirm the importance of seed production from at
462 least the Bronze Age. Although poppy is only present in the dataset from the EBA, it has
463 been recovered from Neolithic contexts further north, though only in very small numbers
464 (Campbell and Robinson, 2007: 24, 33). Both poppy and cabbage/mustard plants were
465 initially/also crop weeds. This Mediterranean domesticate was cultivated during the
466 Linearbandkeramic (Salavert et al., 2020) though its first introduction into Britain may have
467 been as a crop contaminant. Cabbage/mustard (see Fig.1 for taxa included in this category)
468 seeds were most frequent in the Late Bronze Age (LBA) and EIA samples, with the highest
469 count being 142 seeds from EIA Hartshill Copse (site 40). While large deposits of charred
470 black mustard seeds (*Brassica nigra*) are not uncommon from Iron Age sites (e.g. Hartshill
471 Copse (site 40), Brickley Lane in Wiltshire (Pelling, 2002b) and; Bawksbury Camp in
472 Hmapshire (De Moulin, 1996) and Down Farm (Murphy, 1977) in Hampshire), the dataset
473 suggests this practice that cultivating cabbage/mustard may have begun in the LBA in
474 southern England.

Commented [DVA2]: Remove? As suggested by R1

475 Fruits and nuts are assumed to be wild in the early prehistoric period, but may include
476 cultivated and imported varieties by the LIA and Roman period. The impact that the
477 production/consumption of wild resources had on the landscape and its biodiversity cannot
478 be measured through our dataset. Similarly, the effect of individual crop species is not
479 known. However, the evident growth in the representation and density of crop assemblages
480 from the MBA to the Roman period, and its association with increased areas of land under
481 cultivation, is reflected in changing vegetation cover and diversity (Fig.4). Of the seven
482 categories of fruits and nuts (Fig.2b), hazelnut (*Corylus avellana*) is the most frequent and
483 significantly outnumbers cereals in ubiquity in the M/LNEOL and Beaker periods, when crop
484 production is argued to have been marginal in the south-east of England (Stevens and Fuller,
485 2012). However, the same trend is not evident for the other gathered edible taxa,
486 suggesting that the proposed abandonment of cereal cultivation was not visibly replaced by
487 an enriched diet in gathered plant foods. The hawthorn (*Crataegus monogyna*) peaks in the
488 Beaker and EBA periods may be misleading due to the low number of samples; it makes a
489 good leaf fodder and could be associated with the increased focus on pastoralism (Rowley-
490 Conwy et al., 2020; Worley et al., 2019).

491 The possible arable weed assemblages will have been shaped by cultivation practices
492 (intensity and scale), cereal processing stages and variations in the use of cereal processing
493 by-products (Hillman, 1984; Stevens, 2014). Cultivation practices are explored in section 3.2
494 whilst Table 2 clearly demonstrates how taxa and seeds are most numerous in the LBA, ERO
495 and Middle Roman period (MRO). The low representation of ENEOL weeds conforms to the
496 small, low density assemblages common for that period, and may relate to the practice of
497 intensive cultivation that included careful weeding. The very low representation of weeds in
498 the M/LNEOL, Beaker and EBA periods aligns with the poor representation of crops, though
499 the low number of sites and processed volume of sediments for the Beaker and EBA make
500 comparisons difficult. The MBA sees a significant increase in the representation of weeds
501 and the overall density of samples, demonstrating a renewed emphasis on arable
502 cultivation. This trend peaks in the LBA which, after the Early Roman period (ERO), has the
503 highest range of taxa (n=93). The relatively low quantity of weed seeds, despite a high
504 number of taxa (n=83) in the MIA, and the low overall density of samples, is unexpected.
505 The singular results for the MIA are also evident in the other analyses and are discussed
506 below. Similarly, the drop in the density of LRO samples, despite a comparable volume of
507 samples and a greater number of taxa, is also reflected in the analyses below. Since all taxa
508 are included and given equal weighting in the ecological analyses, the MIA and LRO signals
509 cannot be explained by a poorer representation of arable weeds.

Commented [DVA3]: Moved to 3.3

510

511 4.3.23 Multivariate Hierarchical Cluster Analyses

512 Hierarchical cluster analysis (HCA) separated the samples into six clusters with some clear
513 temporal trends (Fig.3). Clusters 1 and 5 are predominantly composed of early prehistoric
514 samples, whilst cluster 6 contains LIA, ERO and MRO samples. Clusters 2, 3 and 4 suggest
515 later prehistoric samples can be separated into three distinct groups. Cluster 5 is composed
516 of almost half of the M/LNEOL samples and is made up entirely of hazelnut. Hazelnut is also
517 common in cluster 1 where cereals, fruits and nuts also occur, but only four arable weed
518 taxa (*Galium aparine*, *Fallopia convolvulus*, *Rumex* sp. and wild legumes). In contrast clusters
519 2, 3, 4 and 6 are influenced by cereal remains and each contain over 30 weed taxa. While
520 the number of Beaker and EBA samples is very low and may not be representative, the
521 inclusion of 20% of EBA samples in clusters 2 and 3 is suggestive of a renewed emphasis on
522 cereal cultivation. M/LNEOL, Beaker and EBA samples are excluded from further ecological
523 analyses below owing to the very low representation of possible arable weeds and the low
524 correlation between the number and volume of samples, and taxa richness.

531
532
533
534
535

Clusters (samples predominantly from..)	Common Taxa (in >50% samples)	N ^o of other taxa
1 (early prehistory)	Hazelnut	15
2 (Iron Age)	Hulled barley grain, bromes, cleavers, indeterminate wild grasses	48
3 (Bronze Age with some Iron Age, mostly MIA, and Roman)	Emmer/spelt grain and chaff, emmer chaff, spelt chaff, indeterminate wild legumes	44
4 (Middle Bronze Age, Early to Middle Iron Age and Late Roman, with some Late Bronze Age and Late Iron Age to Middle Roman)	Emmer/spelt chaff, spelt chaff, indeterminate wheat grains, indeterminate wild grasses	62
5 (Middle/Late Neolithic)	Hazelnut	0
6 (Late Iron Age to Middle Roman)	Hulled barley grain, Emmer/spelt grain and chaff, spelt chaff, indeterminate cereal grain, indeterminate oat grain, ryegrass, corn gromwell, curly dock (<i>Rumex crispus</i>), indeterminate wild legumes, hazelnut	55

536 Table 3: Results of the hierarchical cluster analysis by six clusters, showing taxa present in
537 ≥50% of samples within each cluster (see text for latin binomials)

538

539 Clusters 3 and 4 include the majority of the MBA to LRO samples. These clusters have similar
540 compositions with spelt and/or emmer chaff present in >50% of samples (Table 3). The
541 main difference between the clusters seems to be the presence of emmer, which is less
542 frequent in cluster 4 where IA and Romano-British samples predominate. Both clusters also
543 contain other crops and 32 other weed taxa each, including stinking chamomile (*Anthemis*
544 *cotula*), but corncockle (*Agrostemma githago*) is only present in cluster 4; both species are
545 anthropochores associated with the expansion of cultivation in the Romano-British period
546 (Preston et al., 2004; Stevens and Fuller, 2018). Stinking chamomile is an indicator of clay
547 soils and is associated with the introduction of more robust ploughing technology, such as
548 asymmetrical shares, allowing the expansion of cultivation onto heavier soils (Jones, 1985,
549 2009). However, Roman technology is likely to have been restricted to the more Romanised
550 settlements as it was not until the later Saxon and medieval periods that 'Roman' weeds
551 became prolific (Allen et al., 2017; Stevens and Fuller, 2018: 33). Spelt and emmer grains
552 and chaff are also present in cluster 2, but in fewer than 50% of samples.

553 Cluster 2, which includes EBA, LBA and IA samples, is characterised by hulled barley grain,
554 cleavers (*Galium aparine*), brome (*Bromus secalinus*) and indeterminate wild grass seeds.

555 Barley is also dominant in cluster 6, but in association with oats and ryegrass (*Lolium*
556 *perenne*), rather than brome, as well as corn gromwell (*Lithospermum arvense*) which is
557 indicative of light sandy soils, contrasting with the stinking chamomile and hulled wheats in
558 clusters 3 and 4. The changing weed flora between phases 2 and 6 could indicate a
559 development in the cultivation of barley through the Iron Age and Roman periods (cf.
560 Campbell and Straker, 2003). In addition to cereal remains, cluster 6 also contains fruits and
561 nuts, reflecting the rise in horticulture and exotics during the Roman period (Fig. 2b) (cf. Van
562 der Veen, 2014).

563 Table 2, which lists the number of weed taxa by archaeological period, further helps to
564 understand the classification of samples into clusters. The low representation of ENEOL
565 weeds conforms to the small, low-density assemblages common for that period, and may
566 relate to the practice of intensive cultivation that included careful weeding. The very low
567 representation of weeds in the M/LNEOL, Beaker and EBA periods aligns with the poor
568 representation of crops, though the low number of sites and processed volume of
569 sediments for the Beaker and EBA make comparisons difficult. The MBA sees a significant
570 increase in the representation of weeds and the overall density of samples, demonstrating a
571 renewed emphasis on arable cultivation. This trend peaks in the LBA which, after the Early
572 Roman period, has the highest range of taxa (n=93). The relatively low quantity of weed
573 seeds, despite a high number of taxa (n=83) in the MIA, and the low overall density of
574 samples, is unexpected. The same is true for the LRO where there is a drop in the density of
575 samples, despite a comparable volume and number of taxa to the other Roman periods.

576

577 4.3.13 Land cover, pollen diversity and scale of cultivation (Fig.4)

578 Figure 4: (a) quantified land cover, (each division in the REVEALS and pollen diversity
579 represents a 200year time step from 11,000 BC to present); (b) the density of crops and
580 gathered fruits and nuts (items per litre of deposit) alongside the Shannon diversity of fossil
581 pollen by archaeological period. Note that the chart for crops uses a logarithmic scale
582 whereas the one for fruits and nuts does not as they occur in much lower densities.

583 The densities-concentrations of crops (number of grains, pulses and chaff per litre of
584 deposit) and edible fruits/nuts represent an approximate illustration of the scales of
585 cultivation and gathering activities between periods. The overall relationship between
586 densities of crop assemblages and pollen Shannon diversity is positive and statistically
587 significant. An increase in cultivation is correlated to an increase in vegetation diversity. The
588 bar chart suggests that this relationship is strongest during Early Prehistory. Although
589 changes in assemblage densities reflect changes in settlement patterns and the organisation
590 of crop processing/use, they are also associated with the growth of populations and are
591 here used as a crude measure for the scale of production. The changing densities data
592 through time compare well to the summed probability distribution of radiocarbon dates
593 (SPD) for southern England, which are used as a proxy for fluctuations in population
594 densities (Bevan et al., 2017: Fig. 2a). With the exception of the MIA, the density scores also
595 compare well to the trends in the Shannon diversity indices of fossil pollen (Fig. 4b). The

Commented [DVA4]: Moved to methodology

596 plots provide a useful illustration of how cultivation may have contributed to changes in
597 pollen diversity. Clearing land for cultivation and the type of agriculture practiced (e.g.
598 intensive or extensive; household plots or larger community plots; crop rotation with or
599 without animals) had an impact on the openness of landscapes and their vegetation
600 diversity (De Vareilles et al., 2021; Racimo et al., 2020). The quantified vegetation
601 cover derived from the pollen data using the REVEALS model (Fig.4a) clearly illustrates how
602 the proportion of grassland and cereal land cover increased relative to forest cover when
603 farming was introduced and as the scale of cultivation increased from the MBA to the MRO
604 period.

605 Compared to the Mesolithic, the ENEOL is marked by a decrease in forest cover (Fig.4a). A
606 decline in crop density and increase in the presence of gathered fruits/nuts after the
607 introduction of agriculture is clearly evident (Fig.4b). Whilst this change may represent a
608 shift in human behaviour and depositional activities, it coincides with a slight decline in
609 pollen diversity and increase in forest cover (Fig.4a), suggesting it does reflect a change in
610 landscape use and reduction in arable activity. Crop density then increases from the Beaker
611 period, with a significant increase in the LIA and Roman period. The REVEALS model (Fig.4a)
612 illustrates how the proportion of grassland and cereal land cover increased relative to forest
613 cover when farming was introduced and as the scale of cultivation increased from the MBA
614 to the MRO period. A decline in crop density is seen in the MIA, despite a continued
615 increase in pollen diversity, and again, marginally, during the LRO period. The positive
616 correlation between crop density and pollen diversity appears to change during the LIA
617 when there is a decline in pollen diversity which continues into the LRO.

618

619 The trends in pollen diversity follow the direction of the crop densities up to the MIA. The
620 MIA decrease in crop density is surprising given the general trend towards increasing arable
621 production throughout the Iron Age and into the Roman period, as seen in previous studies
622 (Lodwick, 2017; Stevens, 2014; Van der Veen and O'Connor, 1998). The MIA dip is also
623 evident in other results within this study where this pattern compares more clearly with LBA
624 results. As is explained in section 3.1, sample and site numbers cannot explain the decrease
625 in crop density (Table 2). A population decline could explain the MIA offset, but SPDs
626 indicate an earlier decline between the LBA and EIA, possibly owing to a time of climatic
627 deterioration from a farming perspective (Bevan et al., 2017: 52). The flat shape of the
628 radiocarbon calibration curve covering the Iron Age does make it difficult to assess the
629 length and extent of the population downturn, making it possible that the MIA results
630 reflect this period. Pollen diversity increases slightly in the MIA before reducing continually
631 from the LIA onwards; the gradual reforestation of abandoned settlements and arable fields
632 during a population downturn could result in increased vegetation diversity during the
633 successional stages to woodland. Contrary to the early prehistoric trends, crop density and
634 pollen diversity move in opposite directions during the Roman period, possibly even from
635 the LIA.

636

Commented [DVA5]: Mocvd to discussion

637 4.3.4 Biological and ecological traits (Fig.5)

638 Charred seeds that are not from edible plants, trees, ferns or heather are here considered as
639 potential arable weeds and used to understand past field ecology (see section 2). Traits
640 were attributed to all species and genus where their species have the same attributes. In
641 the previous sections, we have demonstrated that pollen diversity is affected by the scale of
642 cultivation, i.e. the amount of land under cultivation. In this section, we analyse the possible
643 weed floras to gain a better understanding of agrarian practices. The number of samples by
644 phase in the following figures varies as they only include samples for which data are
645 available.

646 Figure 5: The ubiquity of measured characteristics by archaeological period, for five
647 biological/ecological traits. Biological and ecological traits of the possible arable weeds by
648 archaeological period. 'Disturbance' includes plants that flower for no more than 3 months,
649 those that flower for 4 or more months are in the 'high disturbance' category. Beaker and
650 EBA samples are not representative (see 2.1.3). The ubiquity is calculated on the number of
651 samples for which data on a particular trait are available.

652

653 4.3.4.1 Life form (Fig.5a)

654 Three life forms were detected: annuals, plants that can act as both annuals and
655 hemicryptophyte perennials, and hemicryptophyte perennials (perennials that propagate
656 from stoloniferous or rhizomatous roots and benefit from shallow ploughing/disturbance
657 (Bogaard et al., 1999; Jones et al., 2000)). True perennials (plants that take more than a year
658 to grow from seed and regenerate from the same root stock) are not present in any period
659 indicating that even the ENEOL assemblages are from well-established fields rather than
660 recently cleared vegetation (Bogaard, 2002; Rösch et al., 2002). It is also possible that newly
661 established fields were dutifully weeded of perennials and annuals alike, such that the few
662 ENEOL taxa, most of which are twinning, essentially reflect weeding and harvesting
663 techniques. The proportional difference between annuals and hemicryptophyte perennials
664 is similar during the prehistoric and LRO phases, averaging at 25%. This may be an indication
665 of disturbance as well as hand weeding; although shallow cultivation associated with the
666 scratch plough (symmetrical ard that cuts a shallow furrow without inverting the soil) in
667 early prehistory would have encouraged hemicryptophyte perennials, an intensive approach
668 to weeding would have removed visible roots. The difference between life-forms is smallest
669 during the ERO and MRO; perennial roots split and scattered by the plough appear may not
670 to have been removed, enabling them to regrow and seed. The LIA has the highest ubiquity
671 score for annuals (97%) and one of the lowest for hemicryptophyte perennials (60%),
672 suggesting a more careful approach to weeding than in the two preceding and following
673 periods.

674

675 4.3.4.2 Soil texture (Fig.5d)

676 While light, free-draining soil indicators are present in all periods, the plants of heavy soils
677 are also ubiquitous, ~~either pointing to the cultivation of clay-rich soils, perhaps out of~~
678 ~~necessity, or the inadvertent change in soil texture through prolonged shallow ploughing~~
679 ~~which can increase clay concentrations, even creating impermeable horizons~~ (Jones, 1981:
680 111). ~~Geoarchaeological analyses in the Thames Valley show how increased flooding events~~
681 ~~began in the Bronze Age, with continued land clearance resulting in extensive alluviation~~
682 ~~during the Iron Age (Lambrick with Robinson, 2009: 29-34).~~The difference ~~between in~~ the
683 ratio of indicators of heavy to light ~~and heavy~~ soils starts to decline in the LIA and is reversed
684 in the LRO. This trend corroborates the finds of stinking chamomile from the LIA, commonly
685 used to indicate the expansion of cultivation onto heavier soils enabled by deeper ploughing
686 technology (Allen et al., 2017; Lodwick, 2018: 809).

687

688 ~~43.4.53~~ Light intensity (Fig.5ee)

689 The increased proportion of weeds favouring ample sunlight coincides with an increasingly
690 deforested landscape evident from fossil pollen (Fig.4a). These arable weeds may indicate
691 that the increased scale of cultivation involved larger arable fields that, by the nature of
692 their size, were less shaded by surrounding vegetation. In contrast, the arable plots of the
693 ENEOL are noticeably more enclosed.

694

695 ~~43.4.24~~ Soil nitrogen (Fig.5bd)

696 The ENEOL is the only period where weeds favouring very high fertility are the most
697 ubiquitous, which concurs with the intensively managed (i.e. manured) fields deduced from
698 cereal grain isotopic analyses from Lismore Fields, Derbyshire (Bogaard et al., 2013).
699 Indicators of high fertility remain high in all phases, but weeds tolerant of low fertility
700 gradually increase up to the MRO period. The trends suggest that through time soil fertility
701 was not maintained in all arable fields, ~~but that by the LRO though~~ a more intensive
702 approach to manuring may have been adopted during the LRO period. These results
703 corroborate isotopic analyses performed on charred cereal grains from Stanwick
704 (Northamptonshire), that showed a decline in nitrogen isotopes indicative of enriched soils
705 from the MBA to the Roman period (Lodwick et al., 2020). The decline in levels of manuring
706 and associated extensive cultivation practices appears to have begun in the Iron Age ~~and~~
707 ~~different cereals may have been manured to different extents~~. Another, not incompatible,
708 explanation for the decline in the ratio of nitrophile to nitrophobe weeds during late
709 prehistory could be an increase in autumn sowing (Stevens, 2011c). Experiments at
710 Rothampsted (Hertfordshire) have shown that soil nitrogen levels are highest in the spring
711 and tend to decrease rapidly if not maintained, suggesting that a gradual change in fertility
712 indicators may not be due to soil exhaustion (*ibid.*), although little is known of the
713 cumulative effects of different forms of soil management (e.g. crop rotation, green manure,
714 fallow periods, animal fresh/dried manure).

715

716

717

718 4.3.4.35 Flowering onset and duration (Fig.5c-e)

719 Autumn and spring sowing appear to have been practiced in all phases. However, there may
720 be a bias towards spring sowing indicators in enriched soils, where spring weeds would be
721 encouraged (Jones et al., 2000), an effect which could have been particularly strong in the
722 ENEOL. There may also be a bias towards spring sowing indicators generated by the possible
723 uneven representation of cereal processing products and by-products in the dataset. Small
724 seeds, which are more heavily represented in crop-processing by-products (threshing and
725 sieving waste), tend to be from nitrophile spring-germinating weeds (Bogaard et al., 2005;
726 Jones, 1992). Caution is therefore needed in interpreting season of sowing, particularly as
727 crop processing waste is better represented through time (see section 4.3.3-2, Table Fig-3).
728 Taxa tolerant of disturbance, through tilling, weeding, ploughing and/or grazing animals,
729 increase through time up to the LRO period. This signal is reflected in the increased
730 proportion of hemicryptophyte perennials (Fig. 5a, ~~section 3.4.1~~). High levels of disturbance
731 are usually associated with small-scale, intensive cultivation rather than the large-scale,
732 extensive regimes described for the Roman period (Allen and Lodwick, 2017). However,
733 Figures 5a&e may be depicting ~~changes in agricultural regimes and the development and~~
734 ~~increased adoption of agricultural tools and changes to the amount of labour assigned to~~
735 collecting weeds. Deeper ploughing in the LIA to Roman periods, enabled by iron ploughs
736 and animal traction, would have favoured weeds tolerant of more intrusive disturbance. ~~As~~
737 ~~early prehistoric garden type plots neither disturbance tolerant nor intolerant weeds would~~
738 ~~have been at a competitive advantage from effective weeding.~~ Although ubiquity scores are
739 reduced in the LRO, the ratio between disturbance and high disturbance indicators remains
740 comparable throughout the Roman period.

741

742 **54. Discussion**

743 Using presence/absence plant macroremains data and amalgamating all contexts per period into a
744 single assemblage has enabled general temporal trends in land-use to be explored without biases
745 incurred from context and settlement types, and habitation densities. Similarly, calculating the
746 density of crop assemblages by archaeological period provides an indication of changes in the scale
747 of production, and therefore area of land under cultivation as well as land used for all the
748 infrastructure required to process, store and even trade crops. The changing densities data
749 through time compare well to the summed probability distribution of radiocarbon dates
750 (SPD) for southern England, which are used as a proxy for fluctuations in population
751 densities (Bevan et al., 2017: Fig.2a). The statistically significant positive correlation between the
752 density of crop assemblages and pollen diversity demonstrates that cultivation was one of the major
753 practices to affect land cover in prehistory and the Roman period. By comparing results from the
754 plant macroremain dataset to the off-site fossil pollen records, the relationship between arable
755 agriculture and the natural vegetation can be explored. Previous research has demonstrated that
756 increases in population do not, on their own, explain changes in vegetation diversity; how land was
757 used is a crucial factor (Woodbridge et al., 2021). What follows is a discussion of arable practices and

758 vegetation diversity by archaeological period, exploring how developments in the scale and method
759 of cultivation affected land-cover.

760

761 54.1 Early prehistory

762 The introduction of farming in the British Isles instigated localised and small-scale
763 deforestation of deciduous woodlands (Fyfe et al., 2013; Woodbridge et al., 2014). Land-
764 cover changes correspond well to the summed probability distribution (SPD) of radiocarbon
765 dates which suggest a demographic incline during the ENEOL (Bevan et al., 2017; Fig. 1;
766 Shennan et al., 2013; Fig.3). Indeed, the correlation between the arrival of farmers and the
767 decline in deciduous woodland has been shown to be statistically significant (Racimo et al.,
768 2020; see also Marquer et al., 2017). The ENEOL dataset has no clear evidence for the
769 cultivation of newly cleared fields or the repeated use of woodland areas left to regenerate
770 between cycles of cultivation (i.e. shifting cultivation). It is possible that samples from the
771 first generations of farmers are not represented. The results support the arguments for a
772 fixed farming regimes, including the intensive cultivation (high energy input per unit of land)
773 of relatively small fields (cf. Bogaard et al., 2013; Jones and Bogaard, 2017). Nevertheless,
774 these interpretations are based on a restricted range of arable weeds. This is clearly
775 demonstrated by the HCA which grouped ENEOL samples into cluster 1 where only four
776 weed taxa are present, all of which are very difficult to remove, grow in most conditions,
777 produce thousands of small seeds per plants and/or twine around the straw. ~~Across Britain,~~
778 ~~a variety of fix-plot regimes may have existed, as, contrary to results from Lismore Fields,~~
779 ~~isotopic analyse on ENEOL cereal grains from five other sites do not indicate intensive~~
780 ~~cultivation (Bogaard et al., 2013; Treasure et al., 2019). These agricultural practices created~~
781 ~~mosaic-type landscapes of more opened and closed vegetation, promoting small-scale~~
782 ~~niches and driving pollen diversity/ecological novelty (cf. Woodbridge et al., in review).~~
783 Pollen diversity and grassland vegetation increases after the end of the Mesolithic
784 to the Mesolithic, suggesting that the onset of farming can therefore be seen to have had a
785 positive effect on landscape biodiversity, reflected in pollen diversity, initiating marking the
786 onset of a honeymoon period between agricultural land use and biodiversity.

787 A dramatic change in agricultural practises across most of the British Isles is evident from
788 the start of the Middle Neolithic (c.3300 BC). Pollen records point to a regeneration of
789 deciduous woodland (Treasure et al., 2019; Whitehouse et al., 2014) with an associated
790 decline in vegetation diversity (Fig.4). Trends in the SPD of dates on cereal grains show a
791 sharp decline across England, as opposed to the number of dates on hazelnut shells,
792 suggesting that gathered nuts continued to be used whilst the cultivation of cereals was
793 greatly reduced, and even stopped altogether in some regions, such as the south-east of
794 England (Bevan et al., 2017; Stevens and Fuller, 2012, 2015). The proposed abandonment of
795 cereal cultivation in the south-east of England during the M/LNEOL is supported by the
796 dataset. This hypothesis is corroborated by the dataset in which the ubiquity and number of
797 hazelnuts clearly predominates, whilst the interpretation of cereals and pulses is further
798 complicated by the likelihood of intrusive materials (Pelling et al., 2015). The rarity of
799 cereals in later Neolithic assemblages has long been recognised (e.g. Brown, 2007; Jones,

800 1980, Moffett et al., 1989; Robinson, 2000), even though animal domesticates, particularly
801 cattle, continued to be an important dietary element (Serjeantson, 2011). A transition from
802 mainly fixed, agricultural communities to a reduced population of mobile pastoralists is
803 therefore likely. Nevertheless, further work should explain the near absence of edible wild
804 plants other than hazelnuts, large deposits of which are likely to be associated with
805 particular behavioural activities. The abandonment of arable plots, promoting woodland
806 regeneration, presumably resulting from the neglect of arable plots, is associated with a
807 decline in pollen and habitat diversity (Fig.4). Cattle are better adapted to forested
808 landscapes than caprines, which may explain the adoption of a cattle-based mobile
809 pastoralist lifestyle (Serjeantson, 2011; Worley et al, 2019). The shift in lifestyle and decline
810 in human demographics may have been triggered by unstable, colder and wetter climatic
811 conditions (Bevan et al., 2017; Stevens and Fuller, 2015; Whitehouse et al., 2014).
812 Additionally, crop pests and diseases could have contributed towards agricultural collapse
813 (Antolín and Schäfer, 2020; Dark and Gent, 2001). A deterioration in soil quality has also
814 been suggested, as a focus on a narrow range of cultigens by an increasing population may
815 have led to soil depletion and harvest failures (Colledge et al., 2019; Shennan et al., 2013).
816 However, it is unlikely that good quality soils were not available at the limited number of
817 Neolithic sites known in the south-east of England, particularly if small-scale intensive
818 agriculture was practiced.

819 The Beaker period is marked by a new influx of people of central European ancestry by
820 around 2400 BC (Olalde et al., 2018). Changes in material culture, such as the introduction
821 of the Bell Beaker cup, and settlement patterns also attest to a shift in lifestyles (Bradley,
822 2019: chapter 4). Little is known of Beaker subsistence strategies, primarily due to the lack
823 of archaeobotanical and zooarchaeological evidence, although a study of the isotopic
824 signatures in human bone suggests a diet high in terrestrial animal protein with steadfast
825 consistency across Britain (Parker Pearson et al., 2016). The latter study also evidenced a
826 high degree of mobility within Britain, supporting the idea that subsistence strategies
827 continued to be based upon predominantly pastoral lifestyles (Bevan et al., 2017).
828 Archaeobotanical results for the Beaker period are comparable to those for the preceding
829 M/LNEOL, though the very low number of samples may not be fully representative. Even
830 fewer samples are attributed to the EBA and yet the number (and ubiquity) of wheat and
831 barley remains are greatly increased. The classification of EBA samples by the HCA across
832 clusters 1, 2 and 3 suggests a renewed focus on cereal cultivation (Fig.3), as does the
833 regained increase in pollen diversity. The resurgence of cultivation is likely associated with
834 the renewed emphasis on monumentality (e.g. the expansion of Stone Henge), enabled by
835 increased production and reinforcing the dependable and cooperative communities that
836 underpin agricultural economies.

837

838 54.2 The Middle Bronze Age 'agricultural revolution'

839 The resurgence in arable agriculture at around 1600 BC has been termed the Middle Bronze
840 Age agricultural revolution (Stevens and Fuller, 2012). It is clearly demonstrated by the
841 results presented here and is associated with renewed and repeated migrations from the

842 European continent (Patterson et al., 2022). The intensification in land use is evident from
843 pollen records, which show a sharp decrease in woodland cover during the later Bronze Age
844 and the increase in vegetation types indicated by the further decreases in woodland cover
845 and increases clear rise in pollen diversity (Fig. 4). Results from the analyses mark the MBA as
846 the start in a progression towards larger fields of less intensively grown cereals (less
847 weeding and manuring) in an increasingly open landscape. Manuring may have occurred
848 more naturally, through a rotational system. As fields enlarged and the removal of weeds
849 became less efficient, disturbance-tolerant weeds become more evident in the records. The
850 extent to which an enlarged weed flora contributed to the pollen records cannot be
851 ascertained, although greater floral diversity would have supported a greater range of
852 insects. The Middle and Late BA see the greatest rise in pollen diversity and may represent
853 the periods of greatest harmony between agrarian practices and biodiversity. were
854 favoured. The development of field systems and drove ways during the BA, particularly in
855 southern and eastern Britain (Bradley et al., 2016; Yates, 2007), are suggestive of an
856 inclusive use of enclosures, perhaps on a seasonal rotation system, to benefit crops and
857 farm animals, as well as disturbance-tolerant weeds. Indeed, the increase in grassland
858 perennials during the LBA is indicative of the cultivation of fields that had previously been
859 under pasture (Stevens and Fuller 2018: 31). Spelt is a hardier wheat than emmer and its
860 adoption from the MBA has been argued to reflect a change to more extensive arable
861 cultivation (Van der Veen and Palmer, 1997). The change in regime is thought to have been
862 in response to a need for increased cereal production and the quantity and type of farm
863 animals (Van der Veen, 2016: 302). The Bronze Age in southern Britain sees a rise in sheep
864 at the expense of cattle (Hambleton, 2008: 56), animals which cannot provide the same
865 level of manuring or be used to plough fields. It is likely that spelt was initially mixed with
866 emmer, but that, as a result of demographic growth, changes in animal husbandry, its
867 greater adaptability to poorer growing conditions and its higher yielding capacity, spelt
868 became the dominant cereal (Lambrick with Robinson, 2009: 258; Van der Veen, 1995: 342;
869 2016: 301-302). The Bronze Age agricultural intensification is also evident from agricultural
870 tools and features, such as granaries, that became increasingly common during the later BA
871 (Bradley et al., 2016). Fixed wells and waterholes enabled farmers to settle away from main
872 waterways in permanent settlements, thereby expanding the agricultural potential of
873 landscapes (Yates, 2007: 34), and increasing habitat diversity further inland. Insects chart a
874 change from mostly wooded landscapes during the Neolithic and EBA, to open ground
875 associated with pasture and fodder production during the later Bronze Age and Iron Age
876 (Smith et al., 2019, 2020).

877

878 54.3 Late prehistory and the Roman period

879 Britain became more insular towards the end of the LBA, with limited evidence for foreign
880 contacts from both archaeological and palaeogenomic evidence (Cunliffe, 2013; Patterson
881 et al., 2022). A population decline (Bevan et al., 2017) would have led to reduced arable
882 production and the abandonment of settlements/fields, although there is no evidence for a
883 reduction in habitat diversity. The MIA is a period of significant social change, with the

884 emergence of multivallate hillforts encompassing a greater catchment area, indicating a
885 level of social cohesion and organisation not witnessed in the preceding era and an
886 increased political, or at least communal, control over land use in southern Britain (Jones
887 1985, 1996, 2008). Hillforts were abandoned by the LIA and a change in land use is once
888 again visible with the scattering of settlements and new agricultural developments (Cunliffe,
889 1994, 2013). The suggested population decline towards the end of the BA (Bevan et al,
890 2017) is not corroborated by the datasets; there is no evidence for a reduction in the scale
891 of production or habitat diversity. The rate of change between periods appears to slow
892 down, perhaps indicating stability in the scale of production until the MIA. The flat shape of
893 the radiocarbon calibration curve covering the Iron Age does make it difficult to assess the
894 length and extent of the population downturn, making it possible that the MIA results
895 reflect this period. The significant decrease in the density of MIA archaeobotanical
896 assemblages is surprising and cannot be explained by lower sample or site numbers (Table
897 2). It either suggests a change in the depositional activities of crop processing waste (cereal
898 processing and storage may have predominantly occurred in hillforts, but the dataset only
899 includes one MIA hillfort (Danebury: site 22) as most Iron Age hillfort samples are only dated
900 to the Iron Age generally), or a reduction in the production of cereals. Either way, the results
901 suggest that the intensified cereal production indicated for the LIA (Van der Veen and
902 O'Connor, 2008) was not the culmination of a progressive, linear trajectory. Pollen diversity
903 increases slightly in the MIA before reducing continually from the LIA onwards; the gradual
904 reforestation of abandoned settlements and arable fields during a population downturn
905 could result in increased vegetation diversity during the successional stages to
906 woodland. Pollen diversity reaches its maximum during the MIA (Fig.4), suggesting that
907 complex, resilient and varied ecosystems were maintained throughout the earlier Iron Age.

908 The Late Iron Age sees a substantial increase in the scale of production and continued
909 extensive cultivation practices (Figures 4 & 5). The probable cultivation of oat is also evident
910 in our results, as is the surge in wild legumes, brome grass and ryegrass, all common taxa in
911 cluster 6 of the HCA. The Iron Age weed spectrum in central and southern Britain became
912 surprisingly uniform, perhaps indicating that by the LIA agricultural regimes became more
913 influenced by rising market forces or a standardisation in crops and agricultural tools, than
914 by local conditions and choices (Carruthers and Hunter Dowse, 2019: 55). The change in
915 agrarian practices, whereby production became more defined by market forces, may be
916 reflected in the dip in pollen diversity, which is then maintained into the ERO; results
917 suggest that increased and standardised arable production removed some of the diversity
918 present in the prehistoric mosaic of habitats. Wild oat and brome grass became so common
919 that they are often assumed to have been an accepted addition to the crop (Knörzer, 1967;
920 Zech-Matterne et al., 2021), whilst ryegrass might have been an early fodder crop around
921 Danebury (Campbell, 2000). Other common weeds include small grasses, vetches/tares,
922 cleavers and clover types (clover, medicks, trefoil), and are suggestive of the use of grass
923 fallow in a rotation regime (Carruthers and Hunter Dowse, 2019: 55). They are also
924 indicative of a full annual agricultural regime, with crops sown in both autumn and spring.
925 An increase in oat (*Avena* sp.) grains and awns is suggested to represent the LIA cultivation
926 of this potential cereal (Campbell, 2000; Campbell and Straker, 2003). Oat and pea indicate

927 spring sowing, a practise which may have led to growing spelt (in autumn) and spring barley
928 as monocrops rather than as a mixed crop or maslin (Campbell and Hamilton, 2000).

929 Table 2 and Figure 4 show a significant increase in the density of Roman samples, suggesting
930 another surge in arable production. The results corroborate evidence for the expansion of
931 cultivation onto new soils and large-scale, extensive regimes described for the Roman
932 period (Allen and Lodwick, 2017; Campbell, 2017). This appears to precipitate a decline in
933 pollen diversity, suggestive of a reduction in the variation of landscape types, at least in the
934 research area. Throughout prehistory pollen diversity increased with the expansion of
935 agriculture, as forests were cleared for mixed agricultural regimes that encouraged floral
936 and entomological biodiversity (cf. Birks et al., 2016). Results suggest that the tipping point
937 between the expansion of open habitats and the growth of biodiversity may have been
938 reached by in the Roman period. We suggest that the increased scale and extent of arable
939 cultivation during the LIA and Roman period marks at the point in British farming history,
940 when, for the first time, the expansion of cultivation expanded at the expense of had a
941 negative effect on vegetation diversity. The LRO period sees a reduction in arable
942 production associated with the fall of the Roman Empire (Halsall, 2008). The slight increases
943 in the ratio between annuals and perennials and the drop in low fertility indicators in the
944 LRO could suggest a reversal to smaller scale, more intensive cultivation, although this is not
945 matched by a contemporary recovery in levels of pollen diversity (Woodbridge et al., in
946 review). Broad ecological characteristics established during earlier farming regimes may
947 have persisted for longer.

948

949 **65. Conclusion**

950 The use of large-scale archaeobotanical data, over both time and space, and a novel use of
951 HCA, has revealed new details in the development of arable production during the first
952 c.4500 years of agriculture in the south-east of England. Despite differences in behavioural,
953 depositional and taphonomical trajectories between sites and periods, long-term trends in
954 the use of edible plants and cultivation practices are evident. Previously described
955 phenomena, such as the fixed, 'garden'-type cultivation during the ENEOL, the dramatic
956 change in subsistence strategies during the later Neolithic and the significant increase in
957 arable production during the LIA and Roman period are corroborated. Other results indicate
958 that different strategies for collecting and interpreting archaeobotanical remains from the
959 Beaker, EBA and MIA may be required to adequately interpret shifts in subsistence and
960 economic practices. Sites from the two earlier periods require more comprehensive
961 sampling, whilst MIA evidence for cultivation may be concentrated in specific site types.
962 Closer dating of archaeobotanical assemblages is needed to maximise information about
963 temporal development, particularly during the Iron Age. Additionally, the possible Iron Age
964 cultivation of oat needs to be explored through new analytical procedures, such as
965 geometric morphometrics, to overcome the lack of defining chaff (Bonhomme et al., 2017;
966 Wallace et al., 2018).

967 Hierarchical cluster analysis separated the samples not only by the frequency of grains and
968 chaff but also according to the association of different taxa. Neolithic and Beaker samples
969 cluster into two groups: one with only hazelnuts and the other where cereals, but very few
970 weeds, are also present. EBA samples straddle across three clusters, showing similarities
971 with the preceding periods in cluster 1 but also a new, barley-focused assemblage (see also
972 Fig.2a). Clusters 3 and 4 contain assemblages where glume wheat chaff is present in most
973 samples and seem to mark the shift from emmer to spelt cultivation during the Bronze Age.
974 They also demonstrate that crop processing waste is better represented through time. By
975 contrast, clusters 2 and 6 are dominated by barley. The difference between them seems to
976 lie in the presence of brome in cluster 2 and oats and ryegrass in cluster 6, which could
977 indicate a development in the cultivation of barley between the Iron Age and Roman
978 periods.

979 Increased densities of archaeobotanical remains from the Bronze Age to the Roman period
980 are, to some extent, shaped by depositional behaviours related to growing populations, but
981 they also reflect an emphasis on cereal production for a market economy. The surge in the
982 number and range of arable weeds through time reflect a gradual extensification in
983 cultivation and an increase in floral diversity within arable fields. Comparisons with the
984 Shannon diversity of fossil pollen has revealed that arable agriculture influenced changes in
985 landscape types and indicate that early arable farming was not detrimental to biodiversity.
986 Conversely, the onset of farming, increases in crop production and diverse forms of land use
987 practices (varied cropping systems) resulted in elevated levels of biodiversity, reflected by
988 trends in pollen diversity. This honeymoon period for farming and biodiversity was
989 interrupted in the Roman period, when an expanding agricultural economy grew at the
990 expense of biodiversity.

991

992 **Acknowledgements**

993 This research was carried out as part of the Biodiversity and Land-Use Change in the British
994 Isles project funded by the Leverhulme Trust (grant reference RPG-2018-357). We would
995 like to extend our sincere thanks to Jessica Viney for the vital help in uploading data.
