24 asymmetry; Procrustes

25 Short title : Fluctuating asymmetry of dynamic smiles

26 **ABSTRACT**

27 The aim of this study was to use 3D motion facial capture technology to quantify the
28 fluctuating dynamic facial asymmetry, during smiling, in a group of “normal” adults. 54
29 male and 54 female volunteers were recruited. Each subject was imaged using a
30 passive markerless 3D motion capture system (DI4D). Eighteen landmarks were
31 tracked through the 3D capture sequence. Based on either a clinically derived midline
32 or on Procrustes alignment a facial asymmetry score was calculated; based on the
33 Euclidian distance between landmark pairs. Facial asymmetry scores were
34 determined at three-time point; rest, median and maximum frame. Based on both the
35 clinically derived midline and on Procrustes alignment, the differences between males
36 and females, and at the three different time points were not clinically significant.
37 However throughout a smile, facial and lip asymmetry scores increase over the
38 duration of the smile. Fluctuating facial asymmetry exists within individuals, as well as
39 between individuals. The use of Procrustes superimposition or a clinically derived
40 midline produces similar asymmetry scores and is valid for symmetrical faces.
41 However with facial asymmetry, Procrustes superimposition may not be a valid
42 measure, and the use of a clinically derived midline may be more appropriate but this
43 requires further investigation.

44

45 **INTRODUCTION**

46 Facial attractiveness and beauty are important underlying psychological cues in judging
47 an individual's health. Evolutionary psychology proposes that there are four main cues
48 that determine facial attractiveness with respect to mate preference; these are
49 averageness, symmetry, youthfulness and sexual dimorphism¹. Facial symmetry, from
50 a clinical perspective, is probably best thought of as "reflection symmetry"; where
51 features of the face do not change on reflection. Perfectly symmetrical faces do not
52 occur naturally and there is a baseline level of symmetry or "fluctuating asymmetry"
53 between individuals, which is characterized by small random deviations from perfect
54 bilateral symmetry². Individuals with a marked facial asymmetry are known to have a
55 lower quality of life³. Hence one of the aims of facial reconstructive surgery and
56 orthognathic surgery is to minimise facial asymmetry and to correct any clinically
57 significant facial asymmetry respectively. As well as assessing pan-facial symmetry,
58 the symmetry of specific facial regions have been reported, for instance the nasio-
59 labial region in cleft lip and palate patients⁴, the mandible in orthognathic patients⁵, the
60 nose in rhinoplasty patients and the orbits in cranial abnormalities. It is crucial that the
61 clinical team is aware of the site and severity of the asymmetry in comparison to a
62 "normal" group before embarking on surgical correction of the facial deformity.

63

64 Previously, the assessment of static facial symmetry (at rest) in a normal group of
65 individuals has been based on two-dimensional (2D) images, using angular and linear
66 measurements⁶ and statistical shape analysis⁷. The introduction of three-dimensional
67 (3D) imaging has allowed further comprehensive evaluation of static facial symmetry.
68 A recent study assessed the 3D facial symmetry of 20 male and 20 female normal
69 individuals at two discrete time points, i.e. rest and at maximum smile⁸. The study

70 found a statistically significantly higher asymmetry score at maximum smile than at
71 rest based on 27 landmarks. Rather than assessing the expression at rest and
72 maximum smile, dynamic facial asymmetry assessment over the entire smile should
73 be the gold standard. Recently, this has partly been addressed in a comparative study
74 of a small group of non-cleft controls (n=11) with repaired unilateral cleft lip and palate
75 patients (n=12) using 3D motion capture technology⁹. However, only the motion of the
76 upper lip was assessed; at the oral commissure, within the cupid's bow, the cupid's
77 bow peak, upper lip lateral to the cupid's bow and the mid philtral ridge. Although these
78 studies provide some limited information, they either fail to capture the true dynamic
79 nature of smiling or present limited data.

80

81 The development of 3D motion capture technology has allowed capture of non-verbal
82 expressions from rest to maximum expression. To assess reflective symmetry, the left
83 and right sides of the face need to be reflected or mirrored around a mid-facial plane. The
84 mid-facial plane can be clinically determined based on anatomical landmarks, or
85 mathematically derived¹⁰. The later analysis is based on Procrustes "best-fit"
86 superimposition where distances between the original 3D landmark configuration and
87 their mirror image can be calculated and expressed as an "asymmetry score"^{11, 12}.

88

89 The aim of this study is to use 3D motion facial capture technology to quantify the
90 fluctuating dynamic facial asymmetry between a group of clinically "normal" Caucasian
91 adult males and females. The null hypothesis states that there is no difference in the
92 magnitude of overall facial asymmetry, based on the asymmetry score, between
93 genders. In addition, the effects of using a clinically or mathematically derived midline
94 will be investigated.

95

96 **MATERIALS AND METHODS**

97 *Sample size calculation*

98 A pilot study was undertaken to determine the asymmetry scores of a group of 7
99 volunteers with a clinically significant asymmetric smile (assessed by BSK and CL),
100 and 7 individuals with a clinically symmetrical smile. The difference in asymmetry
101 scores of 0.5 determined the threshold of clinical significance. This together with the
102 standard deviation of the differences (0.7), power of 0.8 and statistical difference of
103 (0.0035), following a Bonferroni correction for multiple testing, resulted in a sample
104 size of a minimum of 43 individuals per group.

105

106 *Subjects*

107 Following ethical approval from the Dental Research Ethics Committee (DREC) at the
108 University of Leeds, U.K. (DREC reference 240915/BK/179), 54 male and 54 female
109 volunteers were recruited to take part in the study. Volunteers were recruited if they
110 meet the following inclusion criteria: they were between the ages of 18 and 40 years,
111 no previous facial surgery, no lip piercing, no history of facial trauma or neurological
112 facial problems. In addition subjects recruited were clinically symmetrical and had
113 class I incisors as judged by one experienced Consultant NHS Orthodontist and an
114 orthodontic trainee.

115

116 *Imaging using DI4D™ Pro passive stereophotogrammetric capture system*

117 Each subject was imaged using a passive markerless 3D motion capture system
118 (DI4D, Dimensional Imaging, Hillington, Glasgow). Prior to capture, the system was
119 calibrated according to the manufacturer's instructions. The procedure for capture has

120 been described elsewhere in detail¹³. In summary, each subject practiced the rest
121 position and maximum smile expression until the researcher was happy they had fully
122 understood the facial expression they would need to perform. Following this, the
123 patients were imaged at 60 3D images per second, performing the desired facial
124 expression from rest to maximum smile. Each capture sequence was approximately 3
125 seconds in duration. The captured sequence and appropriate calibration file were
126 imported into the specialised software DIHydra, which generated approximately 180
127 individual 3D images, which were saved for post-capture processing.

128

129 *Post-capture processing*

130 For each subject, the first frame of the sequence was imported into DI3DView
131 software. Using the alignment function, the initial image was re-orientated so the x-
132 plane (axial plane) passed through the inter-canthal line and was parallel to the
133 Frankfort plane, the y-plane (sagittal plane) passed through the mid inter-canthal point
134 at nasion, and the z-plane (coronal plane) passed through the bilateral tragal points.
135 The image was adjusted manually until both operators (BSK and CL) agreed the
136 orientation was correct, Figure 1. The re-oriented 3D image was then saved. The
137 transformation matrix used to re-orientate the initial image was used to re-orientate all
138 of the remaining images in the sequence into the new co-ordinate system. The initial
139 image was landmarked with 22 landmarks (Table 1) and the same landmarks were
140 tracked through the entire image sequence using the automatic tracking function within
141 the software. The accuracy of the automatic landmark tracking algorithm has
142 previously been validated and was found to be clinically acceptable¹⁴. To account for
143 head movement, the forehead landmarks (1 to 4) were used for image stabilisation,
144 while the remaining 18 landmarks were used in the analysis. Finally, the tracked

145 landmark data (x, y and z-coordinates) were exported in .PC2 file format and
146 converted into a format readable by Microsoft Excel using in-house software.

147

148 **ANALYSIS**

149 ***Asymmetry score based on clinically derived midline***

150 The 3D co-ordinate configuration (original configuration) for each frame was imported
151 into MATLAB from the Microsoft Excel file. Firstly, the centroid (geometric centre) of
152 the 18 landmark configuration was computed. Secondly, the 3D configuration was
153 scaled to a common centroid size. Finally, a “reflected” landmark configuration was
154 produced by reflecting the re-scaled original landmark configuration around the sagittal
155 plane, which represented the “clinically derived midline”. An “individual midline
156 configuration” was created by calculating the mean of the original configuration and its
157 reflected version. The Euclidian distances between each of the pairs of landmarks, i.e.
158 the original landmark and the individualised midline, were calculated. The facial
159 asymmetry score was calculated as follows; the Euclidian distance between landmark
160 pairs were squared and summed, then divided by the total number of landmarks
161 (n=18) in the analysis. This procedure was repeated for each of the 3D images in the
162 subject’s 3D capture sequence from rest to maximum smile.

163

164 The higher the facial asymmetry score, the greater the disparity between the landmark
165 pairs and so the greater the degree of facial asymmetry. A score of zero would
166 represent a perfectly symmetrical face. A facial asymmetry score was produced for
167 each individual frame from rest to maximum smile. The facial asymmetry score was
168 recorded at three time points; rest (T_0), median time point (T_1) and maximum smile

169 (T₂). The median time point was defined as the middle frame of the sequence from
170 rest to maximum smile.

171

172 ***Asymmetry score based on Procrustes alignment***

173 As previously described, the 3D facial landmark configuration (original configuration)
174 was imported into MATLAB. New code was written to align the 3D configurations using
175 generalised Procrustes analysis instead of using the clinically derived midline. As
176 before, this involved computing the centroid for each 3D configuration and scaling the
177 configuration to a common centroid size. However, this time the original landmark
178 configuration was reflected around an arbitrary plane, translating and rotating the
179 reflected 3D configuration over the original configuration to achieve “best-fit”. Best-fit
180 was achieved when the sum of the squared distances between the original landmark
181 configuration and its reflected 3D configuration were minimal. For each frame an
182 ‘individual midline configuration’ was created by calculating the mean of the original
183 configuration and its reflected version and the facial asymmetry score was calculated.⁸
184 In addition to the facial asymmetry score based on the 18 landmark pairs, a
185 decomposed lip asymmetry score based on the 10 lip landmarks alone was
186 calculated¹⁵. This method allows facial features, i.e. the lips, which have different
187 numbers of landmarks, to be compared on the same scale.

188

189 **Error study**

190 The error of the method was determined by taking the facial capture sequence of 12
191 volunteers at random and repeating the alignment and landmarking procedure as
192 previously described. The landmarking error was not assessed in isolation, as there
193 would be additional error associated with image re-orientation. There was a period of

194 over 4 weeks between first and second reorientation and landmark digitisations to
195 avoid memory bias. The difference in magnitude of the asymmetry scores as well as
196 the random and systematic error, was assessed between the two digitisations.

197

198 **RESULTS**

199 *Error study*

200 The difference in magnitude of the asymmetry score for the face and lips was less
201 than 0.1 between the two digitisations, Table 2. Systematic error was assessed by
202 paired *t*-tests and random error assessed by coefficients of reliability. No systematic
203 errors were observed and all coefficients of reliability were above 90%.

204

205 *Asymmetry score based on clinically derived midline*

206 *Gender differences*

207 Following a two-sample *t*-test, there were no statistical differences between the female
208 and male facial asymmetry scores at rest ($p=0.363$), median time point ($p=0.559$) and
209 at maximum smile ($p=0.888$). For the lips, males presented with a statistically
210 significantly higher lip asymmetry score than females ($p=0.043$) at the median time
211 point; however the difference in asymmetry score was only 0.18. There were no
212 significant differences in asymmetry scores at rest ($p=0.217$) and at maximum smile
213 ($p=0.284$). As these differences were not clinically significant, the results for males and
214 females were combined for further analysis.

215

216 *Temporal differences*

217 A one-way repeated measures analysis of variance (ANOVA) with a Bonferroni
218 adjustment was used to determine whether there are any statistically significant

219 differences between the facial asymmetry scores at rest, median time point and
220 maximum smile. There was a significantly lower facial asymmetry score at rest (0.76)
221 compared to the median time point (0.93) and maximum expression (0.98). In addition
222 there was as a significant difference between the median time point (0.93) and
223 maximum expression (0.98). This was also the case for the lips; at rest (0.93), at the
224 median time point (1.34) and maximum expression (1.45), Table 3. None of the mean
225 differences or 95% confidence intervals for the facial or lip asymmetry scores between
226 the three time points were greater than 0.5.

227

228 *Asymmetry score based on Procrustes alignment*

229 *Gender differences*

230 Following a two-sample *t*-test there were statistical difference between the female and
231 male facial asymmetry scores at rest ($p=0.041$), median time point ($p=0.001$) and at
232 maximum smile ($p=0.008$). This would not be clinically significant as none of the mean
233 differences or 95% confident limit intervals for the facial or lip asymmetry scores
234 reached the threshold value of 0.5 derived following the pilot study. In all cases males
235 had higher scores than females. For the lips, there was a statistical difference in
236 asymmetry scores between males and females at the median time point ($p=0.002$)
237 and at maximum smile ($p=0.007$). There was no difference at rest ($p=0.064$). Again
238 the differences were sub-clinical and the results for males and females were combined
239 for further analysis.

240

241 *Temporal differences*

242 A one-way repeated measures analysis of variance (ANOVA) with a Bonferroni
243 adjustment showed a significantly lower facial asymmetry score at rest (0.81) than at

244 the median time point (0.99), and at maximum smile (1.02). There was no significant
245 difference between the median time point and maximum smile. For the lips, there were
246 statistical differences in asymmetry score at rest (1.05), median time point (1.42) and
247 at maximum smile (1.50), Table 4. None of the mean differences or 95% confidence
248 intervals for the facial or lip asymmetry scores between the three time points were
249 greater than 0.5.

250

251 **DISCUSSION**

252 It is widely accepted that facial asymmetry is an undesirable characteristic that has a
253 negative impact on the quality of life of an individual³. Currently, quantifying the degree
254 of facial asymmetry is based on static two-dimensional or three-dimensional images.
255 This method of assessment, based on two time points, is unable to capture the
256 dynamic nature of the smile. The present study uses a validated and clinically
257 acceptable imaging modality, passive 3D motion markerless stereophotogrammetry,
258 to capture dynamic facial motion. The system was set to capture the smile at 60 3D
259 frames per second at the correct fidelity. The inclusion criteria, based on assessment
260 of the 3D images and examination of the volunteers, contributed to a “normal”
261 homogenous sample of female and male adult patients. The authors acknowledge the
262 cost and expertise involved in the routine capture of facial dynamics using this
263 technology but such methods could be beneficial to objectively quantify the complex
264 dynamic nature of facial motion following surgical and non-surgical intervention. For
265 example, monitoring the resolution of Bell’s palsy, post-stroke rehabilitation or
266 following facial nerve grafting. Previous studies, based on clinical anthropometric
267 measurements and on static 3D images, have reported a baseline level of asymmetry,
268 at rest, in clinically symmetrical faces between individuals^{8,16,17,18,19,20,21,22}. A statistical

269 difference in asymmetry score, at rest, between genders was not found in the present
270 study, which was in agreement with previously published data^{8,17,20,23}.

271 The present study also found no clinical difference in facial and lip asymmetry scores
272 between males and females half way through the smile (median time point) and
273 maximum smile. Direct comparison of the results with previous studies is not possible
274 as the outcome measures vary between studies. Published outcome measures
275 include asymmetry based on shell-to-shell deviations (root mean square distances)
276 between the original and mirrored facial meshes of individuals^{17,18,19,20}. This method
277 may yield incorrect results as the deviations are based on distances between two
278 nearest points on a surface rather than corresponding points²⁴. In addition the use of
279 Euclidean Distance Matrix Analysis (EDMA) to quantify changes in shape has also
280 been reported²³. Other studies have used landmark analysis and morphometric
281 outcomes to present an “asymmetry index”²². The only study which uses a similar
282 method of analysis and “asymmetry score” found very similar asymmetry scores at
283 rest (0.80) and at maximum smile (0.91)⁸. This was a 3D study and assessed the
284 facial asymmetry score, based on 27 landmarks.

285

286 A novel finding of the present study was that facial asymmetry increases over the
287 duration of the smile in a non-linear fashion. This would suggest that with minimal oral
288 facial musculature activity, faces at rest, are at their most symmetrical. From rest to
289 median smile, individuals have greater scope to smile asymmetrically as there are
290 minimal anatomical constraints. At the extremes of the smile the muscle bundle length,
291 orientation and overlying facia may begin to restrict this ability. This could result in a
292 non-linear increase in asymmetry over time. Hallac et al., (2015) reported the mean
293 asymmetry score from rest to maximum smile based on a small number of controls⁹.

294 Using the mean asymmetry score over the entire duration of the smile may over- or
295 under- estimate the asymmetry score depending on the individual scores or outliers
296 for each frame between rest and maximum smile. The present study uses a specific,
297 well defined, third time point (median frame) between rest and maximum smile for
298 each individual to overcome this problem. Even though there was a statistically
299 significant increase in smile asymmetry over the duration of the smile, it would not be
300 clinically significant. This would be as expected based on the inclusion criteria.

301

302 The asymmetry scores at the three time points based on the clinical midline, and on
303 Procrustes superimposition, were similar. This would be expected as both methods
304 scale the 3D landmark configuration to a common centroid size. Using Procrustes
305 superimposition, the original and reflected configurations are translated to a common
306 centroid position, then rotated to minimise the distances between the landmarks for
307 “best fit”. Using the clinically derived midline, the landmarks are reflected following
308 rescaling. For symmetrical faces there would be minimal translation and rotation
309 during Procrustes superimposition, as the centroids for the original and reflected
310 landmark configurations would be identical in size and similar in location; hence the
311 small differences between the asymmetry scores compared to the clinically derived
312 midline technique. Interestingly, the Procrustes based asymmetry scores were slightly
313 larger than those based on the clinically derived midline. During Procrustes
314 superimposition, all the landmarks will move as the 3D configuration re-orientates and
315 so the distance between landmark pairs will all increase (unless there is absolutely no
316 asymmetry). On the other hand, landmarks in the midline, using the clinically derived
317 midline, will not move and so will reduce the mean score by contributing in number but
318 not in magnitude.

319

320 This is not the case for asymmetrical faces. In this example of an individual presenting
321 with Bell's Palsy affecting the left side of the face, the asymmetry scores are greater
322 when using the clinically derived midline than using Procrustes superimposition,
323 Figure 2. For the global facial asymmetry score, the differences are less marked
324 because the landmark configuration following Procrustes superimposition will re-
325 orientate the entire 3D facial landmark configuration for "best fit". Clinically this would
326 be equivalent to the patient smiling asymmetrically, but changing the orientation of
327 their head to minimise their smile asymmetry. Even though the smile is asymmetric,
328 the displacement of the landmarks around the upper face and eyes during the
329 Procrustes superimposition are contributing to the overall global asymmetry score,
330 Figure 3. Procrustes superimposition is integral in Procrustes analysis, which
331 compares the shape of two objects, for example human skull shapes.²⁵ This method
332 of superimposition works well on static objects. However applying the same technique
333 to a dynamic series of objects i.e. a non-symmetric smiling face forces the "best fit"
334 component of the algorithm to over-ride the need to maintain the orientation of the
335 facial image. In other words shape differences are determined but at the cost of
336 reducing the clinically validity of the outcome. This situation does not occur clinically,
337 and a more clinically valid representation is obtained using the clinically derived
338 midline, where the upper face remains static and the true asymmetry of the smile is
339 seen over the expression of the smile, Figure 4. The use of a clinically derived midline
340 may be controversial but a previous study has shown that "direct manual placement"
341 of geometric vertical midlines on facial images was rated as the best method of
342 determining the midline over automated methods.¹⁰

343

344 In conclusion, fluctuating facial asymmetry exists within individuals, as well as between
345 individuals. The difference between facial and lip asymmetry scores between males
346 and females is probably subclinical. Throughout a smile, facial and lip asymmetry
347 scores increase over the duration of the expression, from rest to maximum smile. The
348 use of Procrustes superimposition or a clinically derived midline produces similar
349 asymmetry scores and is valid for symmetrical faces. However with facial asymmetry,
350 Procrustes superimposition may not be a valid measure, and the use of a clinically
351 derived midline may be more appropriate. A novel baseline data set of dynamic facial
352 and lip asymmetry scores has been presented, which can be used as a yard-stick to
353 compare the outcome of facial surgery or emotion where facial function may be
354 affected.

Table 1 Landmark definitions

Number	Name	Landmark definition
1 - 4	Stabilisation points	Points placed in each corner of the forehead, used as stable points to eliminate head movement.
5	Right Cheilion	Point located at the right labial commissure.
11	Left Cheilion	Point located at the left labial commissure.
6		Point located on the vermilion border midway between right cheilion and right christa philtre.
10		Point located on the vermilion border midway between left cheilion and left christa philtre.
7	Right christa philtre	Point on the right crest of the philtrum, located just above the vermilion border.
9	Left christa philtre	Point on the left crest of the philtrum, located just above the vermilion border.
13	Labrale inferius	Point indicating the lower border of the lower lip.
12		Point midway between right cheilion and labrale inferius.
14		Point midway between left cheilion and labrale inferius.
15	Right subalare	Point on the margin of the base of the right ala where it disappears into the skin of the upper lip.
16	Left subalare	Point on the margin of the base of the left ala where it disappears into the skin of the upper lip.
17	Right exocanthion	Point on the outer commissure of the right eye fissure.
20	Left exocanthion	Point on the outer commissure of the left eye fissure.
18	Right endocanthion	Point on the inner commissure of the right eye fissure.
19	Left endocanthion	Point on the inner commissure of the left eye fissure.
21	Nasion	Point in the midline of the both the nasal root and the nasofrontal suture, always above the line that connects the two inner canthi.
22	Pronasale	Point on the tip of the nose.

Table 2 Error study - the difference in magnitude of the asymmetry score for the face and lips

	Rest (T ₀)		Median time point (T ₁)				Maximum smile (T ₂)					
	Face		Lips		Face		Lips		Face		Lips	
	Mean	SD	Mean	SD	Mean	SD	Mean	SD	Mean	SD	Mean	SD
<i>Asymmetry score based on clinically derived midline</i>	0.1	0.2	-0.1	0.4	0.1	0.2	-0.1	0.3	0.1	0.2	0.0	0.4
<i>Asymmetry score based on Procrustes alignment</i>	0.0	0.1	0.3	0.2	0.0	0.1	-0.1	0.1	0.0	0.1	-0.1	0.2

Table 3 Descriptive statistics showing the differences in asymmetry score, based on clinically derived midline, between females, males and combined values at rest, median and maximum frames for the face and lips during smiling.

	Rest (T ₀)				Median time point (T ₁)				Maximum smile (T ₂)			
	Mean	SD	95% CI		Mean	SD	95% CI		Mean	SD	95% CI	
			Lower	Upper			Lower	Upper			Lower	Upper
Face												
Females	0.77	0.20	0.72	0.83	0.91	0.22	0.87	0.85	0.98	0.26	0.91	1.05
Males	0.76	0.19	0.71	0.81	0.94	0.27	0.87	1.01	0.99	0.33	0.90	1.07
Combined	0.76	0.20	0.73	0.80	0.93	0.24	0.88	0.97	0.98	0.29	0.93	1.04

Combined	1.05	0.27	0.99	1.10	1.42	0.39	1.35	1.50	1.49	0.40	1.41	1.56

Figure legends

- Figure 1 Re-orientated image x-plane (axial plane - green) passed through the inter-canthal line and parallel to the Frankfort plane, the y-plane (sagittal plane - red) passing through the mid inter-canthal point at nasion, and the z-plane (coronal plane - blue) passing through the bilateral tragal points.
- Figure 2 Asymmetry scores based the clinically derived midline than using Procrustes superimposition.
- Figure 3 In an asymmetric, the displacement of the landmarks around the upper face and eyes during the Procrustes superimposition are contributing to the overall global asymmetry score.
- Figure 4 Using the clinically derived midline, the upper face remains static and the true asymmetry of the smile is seen over the expression of the smile. Using Procrustes superimposition the face changes in orientation during smiling, which is not valid clinically.
